(54) Title: **MICRONEEDLE APPARATUS USED FOR MARKING SKIN AND FOR DISPENSING SEMI-PERMANENT SUB-
CUTANEOUS MAKEUP**

(57) Abstract: An array of microneedles is provided to apply semi-permanent or permanent markings to skin, or to apply semi-permanent subcutaneous makeup or other cosmetic compounds to skin. The microneedles can apply identifications or other tattoo-like graphics, and will not enter into the dermal layer of the skin so that the application procedure is painless. The markings can be made permanent or semi-permanent, and can be applied with monochrome or multi-color inks, or even inks that are not visible at human eye wavelengths. The preferred inks contain particles of a certain minimum size that will not diffuse too far through the skin, thereby maintaining a high resolution,

and if placed into the epidermis, the marking will disappear from the skin after a time period. The microneedle array is also useful for delivering specific compounds or actives into the skin, such as cosmetic compounds or nutrients, or various skin structure modifiers that can be delivered subcutaneously without having to visit a cosmetic surgery clinic. In addition, color cosmetics could also be delivered subcutaneously to provide long-term benefits for the skin, and even makeup or lipstick-type coloring compounds can be delivered by use of the microneedle patches described hereinabove. The color cosmetics are delivered into the epidermis, where they remain in place for at least one or two months. Since the epidermis is renewable, the color makeup or color cosmetics that are delivered would eventually wear out, since the epidermis is renewable; the delivered color pigment or dye, or skin structure support actives (such as polymers) will remain in the epidermis for only a finite time (e.g., 1-3 months), and then will be expunged from the body. This allows a person to change their "look" according to changes in fashion and style, which typically change every season.

WO 01/91846 A2

MICRONEEDLE APPARATUS USED FOR MARKING SKIN AND FOR DISPENSING SEMI-PERMANENT SUBCUTANEOUS MAKEUP

TECHNICAL FIELD

The present invention relates generally to medical devices and is particularly directed to a skin marking device and fluid dispensing device of the type which, in one embodiment penetrates the stratum corneum and epidermis, but not into the dermis of skin, so as to inject fluids into the epidermis. The invention is specifically disclosed as an array of microneedles which painlessly and with minimal trauma to the skin enable fluid transfer into the skin as a dispensing device, and can provide color patterns to the skin or provide cosmetic compounds or skin support structures to be semi-permanently placed into the epidermis.

BACKGROUND OF THE INVENTION

Topical delivery of drugs is a very useful method for achieving systemic or localized pharmacological effects. The main challenge in transcutaneous drug delivery is providing sufficient drug penetration across the skin. The skin consists of multiple layers starting with a stratum corneum layer about (for humans) twenty (20) microns in thickness (comprising dead cells), a viable epidermal tissue layer about seventy (70) microns in thickness, and a dermal tissue layer about two (2) mm in thickness.

The thin layer of stratum corneum represents a major barrier for chemical penetration through skin. The stratum corneum is responsible for 50% to 90% of the skin barrier property, depending upon the drug material's water solubility and molecular weight. The epidermis comprises living tissue with a high concentration of water. This layer presents a lesser barrier for drug penetration. The dermis contains a rich capillary network close to the dermal/epidermal junction, and once a drug reaches the dermal depth it diffuses rapidly to deep tissue layers (such as hair follicles, muscles, and internal organs), or systemically via blood circulation.

in the range of 30-50 microns, and provide a trans-dermal or trans-mucous delivery system, which can be enhanced with ultrasound.

Another structure, disclosed in WO 97/48440, WO 97/48441, and WO 97/48442 (by ALZA Corp.) is in the form of a device for enhancing transdermal agent delivery or sampling. It employs a plurality of solid metallic microblades and anchor elements, etched from a metal sheet, with a length of 25-400 μm . WO 96/37256 (by Silicon Microdevices, Inc.) disclosed another silicon microblade structure with blade lengths of 10-20mm. For enhancing transdermal delivery.

Most of the other conventional drug delivery systems involve an invasive needle or plurality of needles. An example of this is U.S. Patent Number 5,848,991 (by Gross) which uses a hollow needle to penetrate through the epidermis and into the dermis of the subject's skin when the housing containing an expansible/contractible chamber holding a reservoir of fluidic drug is attached to the skin. Another example of this is U.S. Patent Number 5,250,023 (by Lee) which administers fluidic drugs using a plurality of solid needles that penetrate into the dermis. The Lee drug delivery system ionizes the drug to help transfer the drug into the skin by an electric charge. The needles are disclosed as being within the range of 200 microns through 2,000 microns.

Another example of a needle that penetrates into the dermis is provided in U.S. 5,591,139, WO 99/00155, and U.S. 5,855,801 (by Lin) in which the needle is processed using integrated circuit fabrication techniques. The needles are disclosed as having a length in the range of 1,000 microns through 6,000 microns.

The use of microneedles has great advantages in that intracutaneous drug delivery can be accomplished without pain and without bleeding. As used herein, the term "microneedles" refers to a plurality of elongated structures that are sufficiently long to penetrate through the stratum corneum skin layer and into the epidermal layer, yet are also sufficiently short to not penetrate to the dermal layer. Of course, if the dead cells have been completely or mostly removed from a portion of skin, then a very minute length of microneedle could be used to reach the viable epidermal tissue.

Since microneedle technology shows much promise for drug delivery, it would be a further advantage if a microneedle apparatus could be provided to sample fluids within

another advantage of the present invention to provide a method of manufacturing an array of microneedles in which a metal mold is initially manufactured for use in a microembossing procedure, while allowing a sufficient separation distance between individual microneedles of the array, then use a procedure for creating hollow chambers and through-holes in the substrate of the microneedle array. It is yet another advantage of the present invention to provide a microneedle array that has sensing capabilities using optical, spectroscopic, colorimetric, electrochemical, thermal, gravimetric, and light scattering sensing means. It is still another advantage of the present invention to provide a method for manufacturing an array of microneedles that uses shear forces during a demolding procedure to create sharp hollow microneedles. It is still a further advantage of the present invention to provide a microneedle array in the form of a microneedle "patch" that dispenses a fluid to apply permanent or semi-permanent markings to skin, or to transfer actives such as cosmetic compounds or skin support structures into the epidermis. It is yet a further advantage of the present invention to provide a microneedle patch that dispenses a fluid to apply permanent or semi-permanent markings to skin, or to transfer actives such as cosmetic compounds or skin support structures into the epidermis by use of an electrically-powered pressure generating actuation system, or by use of a manually actuated membrane. It is still another advantage of the present invention to provide a microneedle patch having solid microneedles to penetrate skin and thereby assist intradermal delivery of solid particles, fluids, or suspensions of particles in a fluid.

Additional advantages and other novel features of the invention will be set forth in part in the description that follows and in part will become apparent to those skilled in the art upon examination of the following or may be learned with the practice of the invention.

To achieve the foregoing and other advantages, and in accordance with one aspect of the present invention, a first embodiment of an improved microneedle array is constructed of silicon and silicon dioxide compounds using MEMS (i.e., Micro-Electro-Mechanical-Systems) technology and standard microfabrication techniques. The microneedle array may be fabricated from a silicon die which can be etched in a microfabrication process to create hollow or solid individual microneedles. The resulting array of microneedles can penetrate with a small pressure through the stratum corneum of

copper, iron, tungsten, and their alloys. The molds alternatively can be fabricated by microfabrication techniques, including deep reactive etching to make silicon, silicon dioxide, and silicon carbide molds. Also, LIGA or deep UV processes can be used to make molds and/or electroplated metal molds.

The manufacturing procedures for creating plastic (or other moldable material) arrays of microneedles include: "self-molding," micromolding, microembossing, and microinjection techniques. In the "self-molding" method, a plastic film (such as a polymer) is placed on a micropillar array, the plastic is then heated, and plastic deformation due to gravitational force causes the plastic film to deform and create the microneedle structure. Using this procedure, only a single mold-half is required. When using the micromolding technique, a similar micropillar array is used along with a second mold-half, which is then closed over the plastic film to form the microneedle structure. The micro-embossing method uses a single mold-half that contains an array of micropillars and conical cut-outs (microholes) which is pressed against a flat surface (which essentially acts as the second mold-half) upon which the plastic film is initially placed. In the microinjection method, a melted plastic substance is injected between two micro-machined molds that contain microhole and micropillar arrays.

Of course, instead of molding a plastic material, the microneedle arrays of the present invention could also be constructed of a metallic material by a die casting method using some of the same structures as are used in the molding techniques discussed above. Since metal is somewhat more expensive and more difficult to work with, it is probably not the preferred material except for some very stringent requirements involving unusual chemicals or unusual application or placement circumstances. The use of chemical enhancers, ultrasound, or electric fields may also be used to increase transdermal flow rate when used with the microneedle arrays of the present invention.

In the dispensing of a liquid drug, the present invention can be effectively combined with the application of an electric field between an anode and cathode attached to the skin which causes a low-level electric current. The present invention combines the microneedle array with electrophoretic (e.g., iontophoresis) or electroosmotic enhancement, which provides the necessary means for molecules to travel through the thicker dermis into or

microneedle is provided having at least one blade with a relatively sharp edge to assist in penetrating the stratum corneum of skin. In a preferred embodiment of a bladed or edged solid microneedle, a three pointed star-shaped solid microneedle is provided in which each blade has a triangular cross-section when viewed from the top of the microneedle, and each of these triangles approximates that of an isosceles triangle. The base of each of the isosceles triangles meets at a center of the microneedle to form a star-shaped structure when seen from the top of the microneedle. At least one hole through the substrate preferably is located near the side surfaces of at least one pair of blades of the solid microneedle, and preferably a through-hole would be located near each pair of such blades. In this preferred embodiment, there would be three edged blades and three adjacent through-holes in the substrate for each microneedle.

In a further alternative embodiment, a porous polymer, such as a hydrogel or solgel matrix can be impregnated with active material and deposited in the inside corners between the blades of the star. This provides an additional delivery mechanism.

The microneedle arrays of the present invention are significantly improved by using a proper separation distance between each of the individual microneedles. A very useful range of separation distances between microneedles is in the range of 100-300 microns, and more preferably in the range of 100-200 microns. The outer diameter and microneedle length is also very important, and in combination with the separation distance will be crucial as to whether or not the microneedles will actually penetrate the stratum corneum of skin. For hollow circular microneedles, a useful outer diameter range is from 20-100 microns, and more preferably in the range of 20-50 microns. For circular microneedles that do not have sharp edges, a useful length for use with interstitial fluids is in the range of 50-200 microns, and more preferably in the range of 100-150 microns; for use with other biological fluids, a useful length is in the range of 200 microns – 3 mm, and more preferably in the range of 200-400 microns.

For circular hollow microneedles having sharp edges (such as those having the blades with triangular shaped edges), a useful length for use with interstitial fluids is in the range of 50-200 microns, and more preferably in the range of 80-150 microns; for use with other biological fluids, a useful length is again in the range of 200 microns – 3 mm, and

creates hollow microneedles, in which the through-holes that normally need to be later created in the substrate have already been created in advance by the first pressing or molding procedure.

Another refinement of the present invention is to create a microneedle array that has sensing capabilities. In this structure, the tips or side grooves of the microneedles are coated with a particular chemical that aids in detecting a particular chemical or biological structure or fluid that come into contact with the tips of the microneedles. A sensing means is performed by the use of optical energy, for example such as a laser light source that is directed through the microneedle structure, in which the microneedles themselves are made of substantially transparent material. Other sensing mechanisms also could be used, as discussed hereinbelow.

A further alternative manufacturing process for hollow or solid microneedles is to create shear forces along the outer surfaces of the distal or tip portion of the hollow or solid microneedle during its molding or embossing process. The shear forces are actually created during the de-molding step while the microneedle array material is being cooled. The amount of shear can be controlled by the cool-down temperature, and if properly done will result in microneedles having sharp edges (rather than smooth edges) along their upper surfaces at their tips.

An array of microneedles is also provided to apply semi-permanent or permanent markings to skin, or to apply semi-permanent subcutaneous makeup or other cosmetic compounds to skin. The microneedles can apply identifications or other tattoo-like graphics, and will not enter into the dermal layer of the skin so that the application procedure is painless. The markings can be made permanent or semi-permanent, and can be applied with monochrome or multi-color inks, or even inks that are not visible at human eye wavelengths. The preferred inks contain particles of a certain minimum size that will not diffuse too far through the skin, thereby maintaining a high resolution, and if placed into the epidermis, the marking will disappear from the skin after a time period.

The microneedle array is constructed in the form of a microneedle "patch" that is attached to the skin at the time the ink is to be transferred from the microneedles to the epidermis. This patch structure can be actuated manually with a human finger, or

forming color patterns if desired.

Still other advantages of the present invention will become apparent to those skilled in this art from the following description and drawings wherein there is described and shown a preferred embodiment of this invention in one of the best modes contemplated for carrying out the invention. As will be realized, the invention is capable of other different embodiments, and its several details are capable of modification in various, obvious aspects all without departing from the invention. Accordingly, the drawings and descriptions will be regarded as illustrative in nature and not as restrictive.

BRIEF DESCRIPTION OF THE DRAWINGS

The accompanying drawings incorporated in and forming a part of the specification illustrate several aspects of the present invention, and together with the description and claims serve to explain the principles of the invention. In the drawings:

Figure 1 is an elevational view in partial cross-section of a bottom mold provided at the initial step of a "self-molding" method of manufacturing an array of plastic microneedles, as constructed according to the principles of the present invention.

Figure 2 is an elevational view in partial cross-section of the mold of Figure 1 in a second step of the self-molding procedure.

Figure 3 is an elevational view in partial cross-section of the mold of Figure 1 in a third step of the self-molding procedure.

Figure 4 is an elevational view in partial cross-section of the mold of Figure 1 in a fourth step of the self-molding procedure.

Figure 5 is an elevational view in partial cross-section of the mold of Figure 1 in a fifth step of the self-molding procedure.

Figure 6 is an elevational view in cross-section of an array of hollow microneedles constructed according to the self-molding procedure depicted in Figures 1-5.

Figure 7 is a cross-sectional view of a top mold-half used in a micromolding procedure, according to the principles of the present invention.

Figure 19 is a cross-sectional view of the semiconductor wafer of Figure 18 after a hole pattern has been established, and after a silicon nitride layer has been deposited.

Figure 20 is a cross-sectional view of the wafer of Figure 18 after a photoresist mask operation, a deep reactive ion etch operation, and an oxidize operation have been performed.

Figure 21 is a cross-sectional view of the wafer of Figure 20 after the silicon nitride has been removed, and after a deep reactive ion etch has created through holes, thereby resulting in a hollow microneedle.

Figure 22 is a perspective view of a microneedle array on a semiconductor substrate, including a magnified view of individual cylindrical microneedles.

Figure 23 is a cross-sectional view of an electrophoretically enhanced body-fluid sensor, based upon a hollow microneedle array, as constructed according to the principles of the present invention.

Figure 24 is a cross-sectional view of an electrophoretically enhanced body-fluid sensor, based upon a solid microneedle array, as constructed according to the principles of the present invention.

Figure 25 is a cross-sectional view of an electrode, based upon a hollow microneedle array, as constructed according to the principles of the present invention.

Figure 26 is a cross-sectional view of an electrode, based upon a solid microneedle array, as constructed according to the principles of the present invention.

Figure 27 is a perspective view of a sensing system attached to a human hand and forearm, which includes an electrophoretically enhanced body-fluid sensor as per Figure 23 and an electrode as per Figure 25.

Figure 28 is a cross-sectional view of an electrophoretically enhanced drug delivery system, based upon a hollow microneedle array, as constructed according to the principles of the present invention.

Figure 29 is a cross-sectional view of an electrophoretically enhanced drug delivery system, based upon a solid microneedle array, as constructed according to the principles of the present invention.

microneedles at a separation distance of 150 microns.

Figure 58 is an elevational view in cross-section of an electrically-powered microneedle patch used for transferring a fluidic multi-color marking or compound to skin, as constructed according to the principles of the present invention.

Reference will now be made in detail to the present preferred embodiment of the invention, an example of which is illustrated in the accompanying drawings, wherein like numerals indicate the same elements throughout the views.

Referring now to the drawings, Figure 1 shows a mold generally designated by the reference numeral 10 that comprises a plurality of micropillars, including micropillars 12 and 14, that are mounted to a base 16 having a planar upper surface 18. Micropillar 12 preferably is cylindrical in shape, and has an outer diameter designated "D1," whereas micropillar 14 (which also preferably is cylindrical in shape) has a diameter designated "D2." The centerlines of micropillars 12 and 14 are separated by a distance "D3," and the vertical height of micropillars 12 and 14 is designated by the letter "L1."

In a preferred configuration, the diameters D1 and D2 are in the range of 1-49 microns, more preferably about ten (10) microns (i.e., 10 microns = 10 micrometers), the height L1 in the range of 50-3000 microns, whereas the separation distance D3 is in the range of 50-1000 microns, more preferably from 50-200 microns.

Microelectrode-discharge machining can be used to fabricate the mold 10 from metals, such as stainless steel, aluminum, copper, iron, tungsten, or other metal alloys. Mold 10 could also be fabricated from silicon or silicon carbide using integrated circuit processing, or photolithographic processing.

Figure 2 depicts the mold 10 and a thin layer of plastic, such as a polymer film, designated by the reference numeral 20, which is placed on the micropillars 12 and 14, thereby making contact at the reference numerals 22 and 24, respectively. Once the polymer film is placed on the micropillars, the polymer is heated to just above the melting temperature of the plastic material. Micropillars 12 and 14 are heated to above the glass transition temperature of the plastic material, but are preferably held below the melting temperature of the plastic material. This establishes a temperature gradient within the plastic film, after which the plastic film is subjected to natural gravitational forces, or placed in a centrifuge. Furthermore, an air-pressure gradient also can be established across the deforming plastic film, by applying pressure from above, or by applying a vacuum from below the film level. The overall effect on the plastic film is that it will undergo a "self-

The inner diameter of the left-hand microneedle 62 is indicated by the distance "D1," and the inner diameter of the right-hand microneedle 64 is indicated by the distance "D2." These distances D1 and D2 are substantially the same distance as the diameter of micropillars 12 and 14, as indicated in Figure 1. Furthermore, the distance D3 between the centerlines of the microneedles on Figure 6 is essentially the same as the distance D3 between the micropillars on Figure 1. The length "L2" of the microneedles on Figure 6 is somewhat less than the length L1 on Figure 1, although this length L2 could theoretically be a maximum distance of L1.

It will be understood that the plastic material (also referred to herein as the "polymer film") may consist of any type of permanently deformable material that is capable of undergoing a gradual deformation as its melting point is reached or slightly exceeded. This "plastic material" could even be some type of metallic substance in a situation where the metallic material would deform at a low enough temperature so as to not harm the mold itself. The preferred material is a polyamide such as nylon, although many other types of polymer material certainly could be used to advantage. Other potential materials include: polyesters, vinyls, polystyrenes, polycarbonates, acrylics such as PMMA, polyurethanes, epoxides, phenolics, and acrylonitriles like acrylonitrilebutadienestyrene (ABS). Of course, one important criterion is that the material which makes up the microneedles does not chemically react with skin, or with the fluidic substance that is being transported through the hollow interiors of the microneedle array.

Figure 7 depicts a top mold-half, generally designated by the reference numeral 110, of a second embodiment of the present invention in which the manufacturing method for creating an array of hollow microneedles is performed by a micromolding procedure. The top mold-half 110 includes two "microholes" that have sloped side walls, designated by the reference numerals 112 and 114 for the left-hand microhole 113, and by the reference numerals 116 and 118 for the right-hand microhole 117. The microholes 113 and 117 have a vertical (in Figure 7) dimension referred to herein as a distance "L11". Microholes 113 and 117 correspond to a pair of micropillars 122 and 124 that are part of a bottom mold-half, generally designated by the reference number 120, and illustrated in Figure 8.

before the next step of the procedure. In Figure 9, the top mold-half 110 is pressed downward and begins to deform the plastic film 130. While a portion of the plastic material 130 temporarily resides above the micropillars at 132 and 134, a larger amount of the plastic material is pressed downward directly by the mold top-half 110 at 140, 142, and 144. As can be seen in Figure 9, the two mold halves 110 and 120 are aligned so that the microholes 113 and 117 correspond axially to the micropillars 122 and 124, respectively. The two mold halves now begin to operate as a single mold assembly, generally designated by the reference numeral 100.

In Figure 10, the two mold halves 110 and 120 have completely closed, thereby squeezing all of the plastic material 130 away from the tops of the micropillars 122 and 124. At this point, the plastic microneedles are formed, and the mold and the plastic material are both cooled down.

The wall 112 and 114 of the first microhole 113 causes a side outer wall to be formed out of the plastic material at 150 and 152. The corresponding inner wall of the microneedle 182 is depicted at 160 and 162, which is caused by the shape of the micropillar 122. Since the outer wall is sloped, it will converge with the inner wall 160 and 162, near the top points at 170 and 172. A similar outer wall 154 and 156 is formed by the inner wall 116 and 118 of microhole 117. The inner wall of the microneedle 184 is depicted at 164 and 166, and these inner and outer walls converge near points 174 and 176.

Figure 11 illustrates the microneedle array, generally designated by the reference numeral 180, after the mold is removed from the plastic material 130. A lower relatively planar base remains, as illustrated at 140, 142, and 144. On Figure 11, two different microneedles are formed at 182 and 184. The angles formed by the walls are as follows: angle A11 by walls 150 and 160, angle A12 by walls 162 and 152, angle A13 by walls 154 and 164, and angle A14 by walls 166 and 156. The points at the top of the microneedles (designated at 170, 172, 174, and 176) are fairly sharp, and this sharpness can be adjusted by the shape of the mold with respect to the microholes and micropillar orientations.

The inner diameter of microneedle 182 is designated by the distance D11, and the inner diameter of the microneedle 184 is designated by the distance D12. The distance

Microhole 213 and micropillar 222 have an angular relationship as illustrated by the angles "A21" and "A22." A similar angular relationship exists for microhole 217 and micropillar 224, as illustrated by the angles "A23" and "A24." These angles A21-A24 will preferably be in the range of zero (0) to forty-five (45) degrees from the vertical. As noted hereinabove, the greater the angle, the greater the transport rate, however, also the greater trauma to the skin tissue when used.

Micropillar 222 preferably has a cylindrical shape with an outer diameter designated at "D21," and micropillar 224 similarly has a preferred cylindrical shape having a diameter "D22." Diameters D21 and D22 preferably are in the range 1-49 microns, more preferably about 10 microns. The distance "D23" represents the separation distance between the center lines of micropillars 222 and 224, which preferably is in the range 50-1000 microns, more preferably in the range of 100-200 microns.

The length of the micropillars from the bottom surface 228 of the top mold-half 210 to the closed end of the microholes at 215 and 225, respectively, is designated as the length "L21." The micropillars 222 and 224 are somewhat longer than this length L21, since they are to mate against the upper surface 242 of the bottom mold-half 240, and therefore are longer by a distance designated as "L25." In this manner, the microneedles will be hollow throughout their entire length. The combined length of dimensions L21 and L25 preferably will be approximately 150 microns.

The molds 210 and 240 will preferably be made from a metal, in which microelectrode-discharge machining can be used to fabricate such metallic molds. Alternatively, the molds could be fabricated from silicon or silicon carbide, for example, using integrated circuit processing or lithographic processing.

Referring now to Figure 13, after the plastic material is heated above its glass transition temperature, thereby causing the plastic material to become sufficient pliable or "soft" for purposes of permanently deforming the material's shape. Preferably, the temperature of the plastic material will not be raised above its melting temperature, although it would not inhibit the method of the present invention for the plastic material to become molten just before the top mold 210 begins to be pressed down against the plastic material 230. This top mold movement begins to deform that plastic material 230 such

constructed in this manner). The height L22 could also be a greater distance for use with other biological fluids, preferably in the range of 200-3000 microns. The thickness L25 can be of any size, however, the important criterion is that it be thick enough to be mechanically sound so as to retain the microneedle structure as it is used to penetrate the skin.

The inside diameter of the hollow microneedles is illustrated as D21 and D22, which correspond to the diameters of a cylindrical hollow opening. The distance D23 represents the separation distance between the centerlines of the two microneedles 282 and 284, in this array 280.

Figure 15A represents an alternative embodiment in which a microneedle array 290 comprises "solid" microneedles 292 and 294, rather than hollow microneedles as seen at 282 and 284 on Figure 15. These solid microneedles 292 and 294 are formed by a similar mold as viewed on Figure 12, but with the micropillars 222 and 224 removed from this mold, and a change in shape of the microholes 213 and 217. This simple change allows the solid microneedles to be formed within conical microholes (not shown on Figure 12), and produces a pointed conical shape, as exhibited by the outer conical wall 250 and 252 for microneedle 292, with a top pointed surface at 296. Similarly, the microneedle 294 has a conical outer wall 254 and 256, with a similar top pointed surface at 298. The other dimensions and features of the solid microneedle array 290 can be exactly the same as those features of the hollow microneedle array 280 of Figure 15, or the dimensions may be different since this is for a different application.

The holes 251, 253, 255, can be fabricated during the microstamping or microembossing procedure via inclusion of appropriate micropillars located adjacent to the microholes 213 and 217 in Figure 12.

Referring to Figure 16, a mold 300 consists of two mold-halves 310 and 340. These mold-halves 310 and 340 are virtually identical in shape, and probably in size, as compared to the mold-halves 210 and 240 of the mold 200 on Figure 12. The main difference in Figure 16 is that these mold-halves are to be used in a microinjection procedure in which molten plastic material is injected from the side at 330 into the opening

dimension L31 on Figure 16, assuming the mold was properly filled with material. A preferred distance for L32 is in the range of 50-200 microns.

The plastic material 330 has a planar base structure, as illustrated at 344, 346, and 348. The thickness of this base structure is the dimension L35. The microneedles themselves exhibit a conical outer wall at 350 and 352 for the left-hand microneedle 382, and at 354 and 356 for the right-hand microneedle at 384. Each microneedle has a hollow interior, as illustrated by the cylindrical surface 360 and 362 for microneedle 382, and 364 and 366 for microneedle 384. These surfaces converge to form points (as illustrated on Figure 17) at 370 and 372 for microneedle 382, and at 374 and 376 for microneedle 384. The convergence angle of these walls is designated by the angles A31-A34, and preferably will be in the range of zero (0) to forty-five (45) degrees.

The inner diameter of microneedle 382 is given by the dimension D31, and for microneedle 384 is given by dimension D32. These dimensions preferably are in the range 1-49, more preferably about 10 microns. The separation distance between the center lines of the microneedles is given at D33, which preferably is in the range 50-1000 microns, more preferably in the range of 100-200 microns. The height L32 is preferably in the range of 50-3000 microns and, depending upon the convergence angle A31-A34, the bottom width of the conical microneedles will vary depending upon the exact application for usage. In one preferred embodiment, this bottom dimension, designated by "D34" and "D35," will be approximately twenty (20) microns. The vertical thickness at L35 will likely be made as thin as possible, however, the important criterion is that it is sufficiently thick to be mechanically sound to hold the microneedle array 380 together as a single structure during actual usage. It is likely that, for most plastic materials that might be used in this molding procedure, the dimension L35 will be in the range of ten (10) microns through two (2) mm, or greater.

The angular relationship between the microneedles and the corresponding planar base surface is preferably perpendicular, although an exact right angle of 90 degrees is not required. This applies to all microneedle embodiments herein described, including microneedles 62, 64 and planar surfaces 30, 32, 34 of Figure 6, microneedles 182, 184 and planar surfaces 140, 142, 144 of Figure 11, microneedles 282, 284 and planar surfaces

preferred to use a double side polish wafer and to grow an oxide layer on the entire outer surface. In Figure 18, a cross-section of this wafer appears as a substrate 410, a top oxide layer 412, and a bottom oxide layer 414. Any single crystal silicon wafer will suffice, although it is preferred to use a crystal structure 100-type wafer, for reasons that will be explained below. A 110-type wafer could be used, however, it would create different angles at certain etching steps.

To create the structure depicted in Figure 19, certain process steps must first be performed, as described below. The first step is a pattern oxide step which is performed on the top side only to remove much of the top oxide layer 412. The pattern used will create multiple annular regions comprising two concentric circles each, of which the cross-section will appear as the rectangles 416 and 418 on Figure 19. In perspective, these annular-shaped features will have the appearance as illustrated on the perspective view of Figure 22 at the reference numerals 416 and 418. These annular oxide patterns are the initial stages of the array locations of the multiple microneedles that will be formed on this substrate 410.

The next step is to deposit a layer of silicon nitride using a low pressure vapor deposition step, which will form a silicon nitride layer on both the top and bottom surfaces of the substrate 410. This appears as the uppermost layer 420 and the bottommost layer 422 and 424. It will be understood that the bottommost layer 422 and 424 is one continuous layer at this step, although it is not illustrated as such on Figure 19, since a later step etches out a portion of the bottom side of the substrate between the layers 422 and 424.

Next in the process is a pattern bottom procedure in which a square hole is patterned beneath the annulus 416, 418, which is not directly visible on Figure 19. The square holes placed by the pattern bottom procedure are now used in a KOH etching step that is applied to the bottom side only of the substrate 410. This KOH etching step creates a window along the bottom of the substrate as viewed along the surfaces 432, 430, and 434 on Figure 19. This window interrupts the oxide layer 414 along the bottom of substrate 410, and divides it (on Figure 19) into two segments 413 and 415. This window

The next step in the fabrication procedure is to remove the silicon nitride layer on the top, which will remove the layer at 426 as seen on Figure 20. This will expose a circular region in the very center of the annulus such that pure silicon is now the outermost material on the top side of the wafer. After that has occurred, a deep reactive ion etch operation is performed to create a through-hole at the reference numeral 460 on Figure 21. After this step has been performed, there will be pure silicon exposed as the inner wall of the through-hole 460. Therefore, the next step is to oxidize the entire wafer, which will place a thin cylindrical shell of silicon dioxide around the inner diameter of through-hole 460, and this oxidized layer is viewed on Figure 21 at 462 and 464.

After these steps have been performed, a microneedle 465 is the result, having an outer diameter at "D41," and an inner diameter through-hole at "D42." It is preferred that the inner diameter D42 have a distance in the range of 5-10 microns. The height of the microneedle is given at the dimension "L41," which has a preferred dimension in the range of 50-200 microns. On Figure 21, the substrate 410 has been divided into halves at 410A and 410B. In addition, the bottom oxide layer 450 has been divided in halves at 450A and 450B.

The bottom chamber formed by the sloped surfaces 452 and 454, in combination with the horizontal surfaces 450A and 450B, act as a small, recessed storage tank or chamber generally indicated by the reference numeral 470. This chamber 470 can be used to store a fluid, such as insulin, that is to be dispensed through the cylindrical opening 460 in the hollow microneedle 465. At the scale of Figure 21, this chamber is not very large in overall physical volume, and it normally would be preferred to interconnect all of such chambers for each of the microneedles in the overall array so that a common fluid source could be used to dispense fluid to each of these chambers 470. Furthermore, there may be a need to dispense a physically much larger volume of fluid, and it also may be desirable to provide a pressure source, such as a pump. In such situations, it may be preferable to have an external storage tank that is in communication with each of the fluid chambers 470 on the wafer that is used to make up the array of microneedles, such as microneedle 465.

Figure 22 depicts an array of microneedles on substrate 410, and also illustrates a magnified view of some of these microneedles 465. Each microneedle 465 exhibits a

Figure 23 depicts an electrophoretically enhanced body-fluid sensor that is based upon a hollow microneedle array, generally designated by the reference numeral 500. Sensor 500 includes a plurality of microneedles 530, which are each hollow, having a vertical opening throughout, as indicated at 532. A fluid chamber 510 is in communication with the hollow portions 532 of the array of microneedles 530. Of course, other fluid driving mechanisms could be used as well, such as passive diffusion (e.g., time release), instantaneous injection, pressure, vacuum, or ultrasound.

Fluid chamber 510 is constructed of a bottom (in Figure 23) planar surface 512—which has openings that are aligned with the microneedles 530—a left vertical wall 514, and a right vertical wall 516. The top (or ceiling) of the fluid chamber 510 is made up of a planar material which is divided into individual electrodes. The middle electrode 525 is part of the fluid sensor, and makes it possible to measure a current or voltage within the fluid chamber 510. Electrodes 520 and 522 are electrically connected to one another (and can be of a single structure, such as an annular ring) so as to act as the electrophoretic electrodes (i.e., as either an anode or a cathode) that facilitate the transport of fluid through the hollow microneedles 530 from the skin into the fluid chamber 510.

The height of the fluid chamber structure is designated as "L50," which could be any reasonable dimension that is large enough to hold a sufficient volume of fluid for a particular application. Of course, if desired, the fluid chamber 510 could be connected to a much larger external reservoir (not shown), and a pump could even be used if pressure or vacuum is desired for a particular application.

The layer 540 represents the stratum corneum, the layer 542 represents the viable epidermis, and the largest layer 544 represents the dermis, which contains nerves and capillaries.

The application of microneedles 530 into the stratum corneum 540 and epidermis 542 decreases the electrical resistance of the stratum corneum by a factor of approximately fifty (50). The applied voltage, therefore, during electrophoresis (e.g., iontophoresis) or electroosmosis can be greatly reduced, thereby resulting in low power consumption and improved safety. Iontophoresis provides the necessary means for molecules to travel through the thicker dermis into or from the body. The combination of the microneedles

and the electric field that is applied between the electrodes 520 and 522 (acting as an anode, for example) and a remotely placed electrode (e.g., electrode assembly 505, viewed on Figure 25, and acting as a cathode, for example) provides for an increase in permeability for both the stratum corneum and the deeper layers of skin.

While the transport improvement in stratum corneum is mostly due to microneedle piercing, the electrophoresis provides higher transport rates in the epidermis and dermis. This is not only true for small sized molecules, but also for the larger and more complex useful molecules.

The body-fluid sampling sensor 500 can be used for a continuous non-invasive measurement of blood glucose level, for example. Glucose is extracted through the skin by reverse iontophoresis, and its concentration is then characterized by a bioelectrochemical sensor. The sensor comprises the chamber 510 that is filled with hydrogel and glucose oxidase, and the electrode 525. The glucose molecules are moved from the body by the flow of sodium and chloride ions caused by the applied electric potential. The detection of the glucose concentration in the hydrogel pad is performed by the bioelectrochemical sensor.

An alternative embodiment 550 is depicted in Figure 24, in which the microneedles 580 are solid, rather than hollow. A fluid-filled chamber 560 is provided and also comprises hydrogel filled with glucose oxidase. The chamber 560 is made of a bottom wall 562 that has openings proximal to the individual microneedles 580, in which these openings are designated by the reference numeral 585. Chamber 560 also includes side walls 564 and 566, as well as electrodes 570, 572, and 575.

The electrode 575 is constructed as part of the bioelectrochemical sensor. The electrodes 570 and 572 act as the electrophoretic electrodes, acting either as an anode or cathode to set up an electric current through the skin which flows to a remotely-attached (to the skin) electrode (e.g., electrode assembly 555, viewed on Figure 26).

As in the sensor 500 of Figure 23, the transport rate of fluids is enhanced by not only the piercing effect of the microneedles 580, but also the electric field inducing a current through the skin. In the glucose sampling example, glucose is attracted into the chamber 560, and its concentration is measured by the bioelectrochemical sensor.

The height of the fluid chamber structure is designated as "L55," which could be any reasonable dimension that is large enough to hold a sufficient volume of fluid for a particular application. Of course, if desired, the fluid chamber 560 could be connected to a much larger external reservoir (not shown), and a pump could even be used if pressure or vacuum is desired for a particular application.

Figure 25 depicts an electrophoretic electrode assembly that is based upon a hollow microneedle array, generally designated by the reference numeral 505. Electrode assembly 505 includes a plurality of microneedles 531, each being hollow and having a vertical opening throughout, as indicated at 533. A fluid chamber 511 is in communication with the hollow portions 533 of the array of microneedles 531.

Fluid chamber 511 is constructed of a bottom planar surface 513—which has openings that are aligned with the microneedles 531—a left vertical wall 515, and a right vertical wall 517. The top (or ceiling) of fluid chamber 511 is made of a planar electrode material 526. The electrode 526 is to be electrically connected to a low-current voltage source (not shown on Figure 25), either through a substrate pathway (such as an integrated circuit trace or a printed circuit foil path) or a wire (also not shown on Figure 25).

The height of the fluid chamber 511 is given by the dimension "L52," which can be of any practical size to hold a sufficient amount of hydrogel, for example, to aid in the conduction of current while acting as the electrode. In electrode assembly 505, the fluid within chamber 511 preferably would not be electrically charged.

As can be seen in Figure 25, the hollow microneedles 531 penetrate the stratum corneum 540 and into the viable epidermis 542. The microneedles 531 preferably will not be sufficiently long to penetrate all the way to the dermis 544.

An alternative embodiment 555 is depicted in Figure 26, in which the microneedles 581 are solid, rather than hollow. A fluid chamber 561 is provided and preferably is filled with hydrogel (which is not electrically charged). Chamber 561 is made of a bottom wall 563 that has openings proximal to the individual microneedles 581, in which these openings are designated by the reference numeral 586. Chamber 561 also includes side walls 565 and 567, as well as a top (or ceiling) electrode 576. The electrode 576 may act as a cathode, for example, in a situation where electrode assembly 555 is being used in

conjunction with a body-fluid sensor, such as sensor assembly 550 viewed on Figure 24, in which its electrodes 570 and 572 may act, for example, as an anode. The height "L57" of fluid chamber 561 could be any reasonable dimension that is large enough to hold a sufficient volume of the hydrogel to enhance the fluid flow via the electric field between the respective anode and cathode of the system.

Figure 27 illustrates a portion of a human arm and hand 590, along with a drug delivery electrode assembly 500 and a second electrode assembly 505. Both electrodes are attached to the skin of the human user, via their microneedles, such as the hollow microneedles 530 (viewed on Figure 23) and the hollow microneedles 531 (viewed on Figure 25).

Since an electrical voltage is applied between the two electrode assemblies 500 and 505, it is preferred to use a low current power supply, generally designated by the reference numeral 596, that is connected to each of the electrodes via a wire 592 or a wire 594, respectively. It will be understood that any type of physical electrical circuit could be used to provide the electrical conductors and power supply necessary to set up an appropriate electrical potential, without departing from the principles of the present invention. In fact, the electrode assemblies and wiring, along with an associated power supply, could all be contained on a single apparatus within a substrate, such as that viewed on Figures 30 and 31 herein, or by use of printed circuit boards.

Figure 28 depicts an electrophoretically enhanced fluidic drug delivery apparatus that is based upon a hollow microneedle array, generally designated by the reference numeral 600. Drug-delivery apparatus 600 includes a plurality of microneedles 630, which are each hollow, having a vertical opening throughout, as indicated at 632. A fluid chamber 610 is in communication with the hollow portions 632 of the array of microneedles 630.

Fluid chamber 610 is constructed of a bottom (in Figure 28) planar surface 612—which has openings that are aligned with the microneedles 630—a left vertical wall 614, and a right vertical wall 616. The top (or ceiling) of the fluid chamber 610 is made up of a planar material 620 that acts as an electrode. Electrode 620 is part of the drug delivery apparatus, and makes it possible to induce a current flow through fluid chamber 610.

Electrodes 620 and 622 are connected so as to act as the electrophoretic electrodes (i.e., as either an anode or a cathode) that facilitate the transport of fluid through the hollow microneedles 630 from the fluid chamber 610 into the skin.

The height of the fluid chamber structure is designated as "L60," which could be any reasonable dimension that is large enough to hold a sufficient volume of fluid for a particular drug delivery application. Of course, if desired, the fluid chamber 510 could be connected to a much larger external reservoir (not shown), and a pump could even be used if pressure or vacuum is desired for a particular application.

The layer 540 represents the stratum corneum, the layer 542 represents the viable epidermis, and the largest layer 544 represents the dermis, which contains nerves and capillaries.

The application of microneedles 630 into the stratum corneum 540 and epidermis 542 decreases the electrical resistance of the stratum corneum by a factor of approximately fifty (50). The applied voltage, therefore, during electrophoresis (e.g., iontophoresis) can be greatly reduced, thereby resulting in low power consumption and improved safety. Iontophoresis provides the necessary means for molecules to travel through the thicker dermis into or from the body. The combination of the microneedles and the electric field that is applied between the electrodes 620 and 622 (acting as anodes, for example), and another electrode (e.g., electrode assembly 505, acting as a cathode) that is attached elsewhere on the skin of the user, provides for an increase in permeability for both the stratum corneum and the deeper layers of skin. While the transport improvement in stratum corneum is mostly due to microneedle piercing, the electrophoresis provides higher transport rates in the epidermis and dermis. This is not only true for small sized molecules, but also for the larger and more complex useful molecules.

The drug delivery apparatus 600 can be used for a continuous non-invasive medical device that can continuously deliver a fluidic drug through the skin and into the body. For example, insulin could be delivered to the blood stream via the microneedles 531, through the stratum corneum 540 and epidermis 542, and also into the dermis 544 where the insulin would be absorbed into the capillaries (not shown).

An alternative embodiment 650 is depicted in Figure 29, in which the microneedles 680 are solid, rather than hollow. A fluid-filled chamber 660 is provided and also contains hydrogel. Chamber 660 is made of a bottom wall 662 that has openings proximal to the individual microneedles 680, in which these openings are designated by the reference numeral 685. Chamber 660 also includes side walls 664 and 666, as well as electrodes 670, 672, and 675.

The electrode 675 is constructed as part of the bioelectrochemical sensor. The electrodes 670 and 672 act as the electrophoretic electrodes, acting either as the anode or cathode to set up an electric current through the skin, in conjunction with another electrode assembly (such as electrode assembly 655, viewed on Figure 26) placed elsewhere on the user's skin.

As in the drug delivery apparatus 600 of Figure 28, the transport rate of fluids is enhanced by not only the piercing effect of the microneedles 680, but also the electric field inducing a current through the skin. In the insulin dispensing example, insulin is repelled from the chamber 660, and therefore, flows out through openings 685 proximal to microneedles 680, then into the user's skin.

The height of the fluid chamber structure is designated as "L65," which could be any reasonable dimension that is large enough to hold a sufficient volume of fluid for a particular application. Of course, if desired, the fluid chamber 660 could be connected to a much larger external reservoir (not shown), and a pump could even be used if pressure or vacuum is desired for a particular application.

Figure 30 depicts a closed-loop drug-delivery system generally designated by the reference numeral 700. This closed-loop system 700 includes a pair of electrophoretic pads, generally designated by the reference numerals 500 and 505, which each include an array of microneedles for fluid sampling. Pad 500 comprises a sensor assembly (as described hereinabove with respect to Figure 23), and pad 505 comprises an electrode assembly (as described hereinabove with respect to Figure 25).

Closed-loop system 700 also includes a pair of electrophoretic pads, generally designated by the reference numerals 600 and 605, that each include an array of microneedles for drug delivery. Pad 600 comprises a drug delivery apparatus (as

described hereinabove with respect to Figure 28), and pad 505 comprises an electrode assembly (as described hereinabove with respect to Figure 25). Of course, electrophoretic pads having solid microneedles could instead be used, such that pads 500 and 600 (with hollow microneedles) could be replaced by pads 550 and 650 (with solid microneedles), and pad 505 (with hollow microneedles) could be replaced by a pad 555 (with solid microneedles).

Pads 500 and 600 are mounted to a substrate 710, which can be made of either a solid or a somewhat flexible material. Within substrate 710 preferably resides a reservoir 712 (within the substrate 710) that holds the fluid which is to be dispensed through the microneedles of pads 600. Reservoir 712 could be made up of individual "small" chambers, such as a large number of chambers 610 that are connected to a source of fluidic drug.

It will be understood that the reservoir 712 preferably is completely contained within substrate 710, and cannot be seen from this view of Figure 31. As an alternative, however, a fluid channel (such as a flexible tube at 730) could be connected into substrate 710 and, by use of a pump (not shown), further quantities of the fluid could be provided and dispensed through the microneedles of pads 600, using fluidic pressure.

Figure 31 illustrates the opposite side of the closed-loop system 700. A controller 720 is mounted to the upper surface (in this view) of substrate 710. Controller 720 preferably comprises a type of microchip that contains a central processing unit that can perform numeric calculations and logical operations. A microprocessor that executes software instructions in a sequential (or in a parallel) manner would be sufficient. A microcontroller integrated circuit would also suffice, or an ASIC that contains a microprocessor circuit.

Adjacent to controller 720 is an electrophoretic power supply with a battery, the combination being generally designated by the reference numeral 722. In addition, a visual indicator can be placed on the surface of the substrate, as at 730. This visual indicator could give a direct reading of the quantity of interest, such as glucose concentration, or some other body-fluid parameter. The visual indicator preferably comprises a liquid crystal display that is capable of displaying alphanumeric characters, including numbers.

While a pumping system that creates fluid pressure could be used for dispensing a fluidic drug into a body through hollow microneedles, such as emplaced on pads 600, in many instances it is preferred to use an electrophoresis method to enhance the delivery of the drugs through the microneedles. As discussed hereinabove, application of microneedles can decrease the electrical resistance of the stratum corneum by a factor of fifty (50), and so the voltage necessary to facilitate electrophoresis can be greatly reduced, improving safety and requiring much less power consumption. By use of the electrophoresis, the molecules making up the fluid drug will travel through the thicker dermis into or from the body, and the combination of both transport-enhancing methods provides an increase in permeability for both the stratum corneum and the deeper layers of the skin. The transport improvement in the stratum corneum is mostly due to microneedle piercing, although the electrophoresis provides higher transport rates in the epidermis and dermis.

The closed-loop drug-delivery system and fluid-sampling system 700 can be used for continuous noninvasive measurement of blood glucose level by extracting, via reverse iontophoresis, glucose through the skin and measuring its concentration by the bioelectrochemical sensor (such as the sensor constructed of the hydrogel chamber 510 and sensor electrode 525, along with the controller 720). The hydrogel pads containing microneedles (i.e., pads 500) enhance the reverse iontophoresis to move glucose molecules from the body by the flow of sodium and chloride ions, which are caused by the applied electric potential via electrodes 520 and 522. Once the glucose concentration is measured within the hydrogel pads 500, the proper amount of insulin, for example, can be dispensed through the other pair of pads 600 that make up part of the closed-loop system 700.

As discussed hereinabove, drug delivery is performed by applying an electric potential between two microneedle array electrodes. One of the electrodes is filled with an ionized drug (such as insulin), and the charged drug molecules move into the body due to the electric potential. Controller 720 will determine how much of a drug is to be dispensed through the microneedle array 600 at any particular time, thereby making the closed-loop system 700 a "smart" drug-delivery system.

This smart drug-delivery system can be used as an artificial pancreas for diabetes patients, as a portable hormone-therapy device, as a portable system for continuous outpatient chemotherapy, as a site-specific analgesic patch, as a temporary and/or rate-controlled nicotine patch, or for many other types of drugs. Such systems could be made as a disposable design, or as a refillable design.

It will be understood that the closed-loop system 700 can be used in many applications, including as a painless and convenient transdermal drug-delivery system for continuous and controlled outpatient therapies, a painless and convenient body-fluid sampling system for continuous and programmed outpatient body-fluid monitoring, as a high-rate transdermal drug delivery system, or as a high-accuracy transdermal body-fluid sampling system. More specifically, the closed-loop system 700 of the present invention can be used as a portable high-accuracy painless sensor for outpatient blood glucose-level monitoring, as a portable system for continuous or rate controlled outpatient chemotherapy, as a temporary and rate controlled nicotine patch, as a site-specific controlled analgesic patch, as an externally attached artificial pancreas, as externally attached artificial endocrine glands, as temperature-controlled fever-reducing patches, as heart rate-controlled nitroglycerin high-rate transdermal patches, as temporarily controlled hormonal high-rate transdermal patches, as erectile dysfunction treatment high-rate transdermal patches, and as a continuous accurate blood-analysis system. Another use of the closed-loop system 700 of the present invention is to form a portable drug delivery system for outpatient delivery of the following drugs and therapeutic agents, for example: central nervous system therapy agents, psychic energizing drugs, tranquilizers, anticonvulsants, muscle relaxants and anti-parkinson agents, smoking cessation agents, analgetics, antipyretics and anti-inflammatory agents, antispasmodics and antiulcer agents, antimicrobials, antimalarias, sympathomimetic patches, antiparasitic agents, neoplastic agents, nutritional agents, and vitamins.

It will be understood that various materials other than those disclosed hereinabove can be used for constructing the closed-loop system 700, and for constructing individual body-fluid sampling sensors and individual drug-delivery systems. Such other materials could include diamond, bio-compatible metals, ceramics, polymers, and polymer

composites, including PYREX®. It will yet be further understood that the electrophoretically/microneedle-enhanced transdermal method of transport of the present invention can also be combined with ultrasound and electroporation, in order to achieve high-rate drug delivery into individual cells.

It will also be understood that the length of the individual microneedles is by far the most important dimension with regard to providing a painless and bloodless drug-dispensing system, or a painless and bloodless body-fluids sampling system using the opposite direction of fluid flow. While the dimensions discussed hereinabove are preferred, and the ranges discussed are normal for human skin, it will further be understood that the microneedle arrays of the present invention can be used on skin of any other form of living (or even dead) creatures or organisms, and the preferred dimensions may be quite different as compared to those same dimensions for use with human skin, all without departing from the principles of the present invention.

It yet will be understood that the chemicals and materials used in the molds and dies can be quite different than those discussed hereinabove, without departing from the principles of the present invention. Further, it will be understood that the chemicals used in etching and layering operations of microfabrication discussed above could be quite different than those discussed hereinabove, without departing from the principles of the present invention.

Figure 32 illustrates another alternative embodiment of a hollow microneedle, generally designated by the reference numeral 800. The main body of the microneedle 800 has a generally cylindrical shape, as indicated by its outer surface at 802. A generally circular opening creates a hole at 806 through which fluids can pass. The cylindrical shape is preferably maintained throughout the length of microneedle 800, so that its bottom profile would also maintain a generally circular shape, as depicted at 810. Of course, minor variances in this shape could be utilized without departing from the principles of the present invention, such as an elliptical shape for its cross-section (rather than a circular shape), for example.

The general cylindrical shape is preferably maintained also at the top portion, as seen by the outer wall at 808. The top surface at 804 will have the form of a pair of

concentric circles, in situations where the opening 806 is circular. The bottom portion at 810 of microneedle 800 is abutted to a base element having a generally planar surface at 805. In a preferred mode of construction, microneedle 800 and the surface 805 would be of a unitary construction, i.e., it would be formed from a single piece of material. This single piece of material would preferably be a molded plastic or like material, or a cast metal or like material. Of course, composite materials could also be utilized.

One primary advantage of the shape of microneedle 800 is that it has a pair of sharp edged projections at 820 and 830 that aid the penetration of the outer surface (i.e., stratum corneum) of the skin, thereby requiring less force to be applied when using an array of such microneedles 800. Each edged projection or blade 820, 830 has a cross-sectional shape that is generally triangular when viewed from the top of microneedle 800 (see Figure 33). The exact shape of the triangle will depend upon the strength requirements of each of the blades 820, 830, the material used to construct microneedle 800, and the amount of skin damage that is allowable in a particular usage application. The preferred cross-sectional shape is that of an isosceles triangle having a base angle in the range between 1 and 45°. Of course, a rounded contour could be used instead of straight walls for the blade surfaces, without departing from the principles of the present invention.

The illustrated blade 820 has an upper generally triangular surface at 822, and one of its side walls is represented by the planar surface at 824, as seen on Figure 32. A similar planar wall is on the opposite side at 836 (see Figure 33), and the junction of these two planar walls 824, 826 forms a generally sharp edge, as depicted at the reference numeral 828.

The second protrusion or blade 830 is similarly formed of two generally planar side walls at 834 and 836 (see Figure 33), which also join at a generally sharp edge at 838. The upper surface of the blade 830 is depicted at 832 as having a generally triangular shape, in the illustrated embodiment.

It will be understood that either less or more than two sharpened blade projections could be utilized in the microneedle 800 of Figure 32 without departing from the principles of the present invention, although the two blades 820 and 830 are an optimal design.

As illustrated on Figure 33, the inner diameter of the opening 806 is depicted at the reference numeral 842, and the outer diameter of the microneedle 800 is depicted at the reference numeral 840. The size of the outer diameter of microneedle 800 is very important as to its penetrating capabilities into the skin, whereas the inner diameter 842 is of lesser importance in that regard. However, the inner diameter 842 must be large enough to easily pass the desired molecules of the fluid to be passed therethrough.

Figure 34 illustrates a similar hollow microneedle, generally designated by the reference numeral 850. This alternative embodiment microneedle 850 also includes two longitudinal blade structures at 870 and 880, and also is of a generally cylindrical shape throughout most of its length from its base element's bottom surface at 855 to its top surface at 854. The opening at 856 is also generally circular in situations where the microneedle 850 is of cylindrical shape. Of course, the overall outer shape of the microneedle 850 and the inner shape of the opening 856 could be somewhat non-circular (such as an ellipse) without departing from the principles of the present invention.

In Figure 34, microneedle 850 could be constructed of a molded plastic or a cast metal material, but in this particular representation the microneedle 850 is constructed using semiconductor fabrication techniques. The first blade 870 has a generally planar side wall at 874, and in conjunction with a similar side wall not shown on Figure 34, forms a generally sharp edge at 878. The cross-section profile of this blade structure 870 is seen at 872, as having a generally isosceles triangular shape, although more rounded side walls could be utilized without departing from the principles of the present invention. On Figure 34, this sharp edge 878 does not continue all the way to the bottom surface 855 of the microneedle base structure, but instead continues down to a point where the blade structure discontinues, as illustrated at 862. This could be utilized to create a greater yield of microneedle structures using semiconductor fabrication techniques, or could be utilized to create a structure having greater mechanical strength near the bottom areas (e.g., at the side wall area 864) of the microneedle 850. When using this type of shape for the structure of microneedle 850, the outer diameter of the microneedle has the form shown at 860 as it joins the planar bottom surface 855. This shape at 860 could be generally semi-circular, but also could be of a larger diameter to provide greater mechanical strength than

the outer diameter near the top surface 854 of microneedle 850.

The second blade 880 has a similar top profile at 882, and a similar sharp edge at 888. The side wall structure near the bottom of the second blade 880 is not viewable in Figure 34, but can be inferred from the shape of the bottom sidewall at 864.

Other variations in shape of the microneedle structures depicted in Figures 32 and 34 could be utilized without departing from the principles of the present invention. The primary goals are to create mechanically sound structures that can penetrate the stratum corneum of human skin (or other type of animal or even plant skin), and the sharp longitudinal blade structures are a great improvement over such hollow microneedles that do not have these side blades, enhancing penetration of drugs through the skin. It will be understood that the microneedle structures depicted in Figures 32 and 34 could be constructed of any materials and by any type of fabrication techniques, without departing from the principles of the present invention.

Another variation in the hollow microneedles depicted on Figures 32 and 34 would be to have a top surface that is not generally flat, but instead has a arcuate or parabolic top surface as seen from one of the sides of the microneedle structure. This type of structure could either be machined, or could be generated during de-molding, as illustrated in Figures 57A and 57B, discussed hereinbelow.

An alternative solid microneedle shape is depicted in Figures 35 and 36, in which the solid microneedle is generally star-shaped in profile. As viewed from its top surface (see Figure 36), the solid microneedle 900 is a generally three-pointed star shape, having three longitudinal blades at 910, 920, and 930. The top surface of each of these star-shaped blades is depicted at 914, 924, and 934, and as can be seen from Figures 35 and 36, a major portion of these top surfaces is generally triangular in shape. The preferred shape is that of an isosceles triangle, in which the base angle of this triangle is in the range of 1-45°. Of course, the smaller this base angle, the smaller the amount of skin damage done when the microneedle 900 is inserted into the stratum corneum.

Each blade 910, 920, and 930 has a pair of generally planar side walls at 912, 913, 922, 923, 932, and 933 (although these side walls could be somewhat curved in contour, if desired). These side walls converge to form a generally sharp point at 918, 928, and

938, respectively. In the illustrated embodiment of Figure 35, microneedle 900 continues this star-shaped profile from its top surfaces at 914, 924, and 934 down to its bottom edges at 916, 926, and 936, where the microneedle structure joins its top planar base structure at 905. Of course, the very upper surfaces are most key as far as making a penetration into the skin through the stratum corneum, and the precise shape of the blades 910, 920, and 930 may somewhat vary along the longitudinal length of microneedle 900 without departing from the principles of the present invention. The major benefit of this shape is its small cross-sectional area allowing easy insertion into the skin, yet a large surface area providing high rates of active penetration through the skin.

Since microneedle 900 is solid, for liquid to be dispensed into the skin or to be sampled from the skin, a set of openings is provided in the base element or substrate at 908. It is preferred that a single opening be located along each pair of projections or blades, as illustrated on Figure 36, in which an opening 940, 942, and 944 is provided between the blades 910-920, 920-930, and 930-910, respectively. Of course, different sized holes and different hole locations, as well as different numbers of holes for that matter, could be utilized with the solid microneedle 900, without departing from the principles of the present invention.

Microneedle 900 could be constructed of virtually any material that is biocompatible with human skin (or other animal or plant skin). This includes molded plastic or cast metal, or perhaps a silicon or silicon-dioxide structure that is manufactured using semiconductor and plastic fabrication techniques. The top surface at 914, 924, and 934 is illustrated as being generally planar, although this could be changed easily enough to cause the mid-portions of the microneedle 900 to be somewhat lower than the points of the three blades at their top edges 918, 928, and 938. Such a construction would have a similar side appearance to the hollow microneedle 1420 depicted on Figure 57B.

It will be understood that more or less than three blades could be constructed to create a solid microneedle such as that of microneedle 900, without departing from the principles of the present invention. Even a single blade design could be used, having either one or two sharp edges. While the three-bladed solid microneedle 900 is of an optimal design, certainly a four-bladed design could also be manufactured and used, and provide

generally good results. In a four-bladed design, it would be preferred that each pair of blades have a corresponding through-hole in the substrate beneath the bottom portion of the solid microneedle, although such holes are not necessarily required between each pair of blades. The size of each of the through-holes such as holes 940, 942, and 944 is up to the designer, although its inner diameter should be sufficiently large to allow useful molecules to pass therethrough.

Another very important attribute of arrays of microneedles is the separation distance between each of the microneedles with regard to their placement on the substrate or base structure. On one hand, the more microneedles per given area of a substrate, the greater the amount of "transdermal flux" (or transdermal flow) of a fluid that will be transported through the microneedles (i.e., in the case of hollow microneedles). On the other hand, it has been determined that the closer the spacing of microneedles, the less likely that the microneedles will actually penetrate the stratum corneum layer of skin due to the elasticity characteristics and mechanical strength of skin. Therefore, a dichotomy exists that indicates the separation between microneedles is critical for a useful device.

Figures 37-42 provide tabular data illustrating the effects of microneedle length, microneedle outer diameter, and microneedle separation for circular hollow microneedles, such as those depicted in Figure 15, Figure 22, and Figures 25 and 28. As related hereinabove, the microneedles illustrated in these figures are hollow, having internal cylindrical openings, but are not edged or sharpened with respect to having any type of blade structure along their outer surfaces or tips. Furthermore, the tabular data of Figures 37-42 are with respect to microneedles that are arranged in a hexagonal configuration. All dimensions on these Figures 37-42 are in microns (i.e., micrometers). Each chart shows ten rows that represent various microneedle lengths in the range of 30-300 microns, and ten columns showing microneedle outer diameters in the range of 10-100 microns. Each chart is for a different separation distance, starting with 50 microns, and then incrementing by 50 microns to the final chart of Figure 42 that shows a separation of 300 microns.

The table entries of "Y" represent a situation where the microneedle penetrates the skin. A table entry of "n" represents a configuration where the microneedle will not penetrate skin. Finally, the "diamond" shape represents a table entry in which the

microneedle will possibly penetrate the skin, however, it is not certain that penetration will occur.

Each table contains a dashed line (such as line 1002 on Figure 37) that roughly indicates that table entries below the line will likely penetrate the skin, whereas table entries above the line will likely not penetrate the skin. These lines represent approximations to a certain extent, and a tolerance of at least plus or minus 10% should be considered when utilizing this data. In some circumstances, the tolerance should be more like plus or minus 20%.

On the various charts, the lines are indicated at 1002 for Figure 37, 1004 for Figure 38, 1006 for Figure 39, 1008 for Figure 40, 1010 for Figure 41, and 1012 for Figure 42. Each of these lines can be approximately defined by an equation, in which the variables are microneedle length represented by "L," and the outer diameter represented by the variable "D." For these equations, all dimensions are in microns. In Figure 37, the equation is: $L = 9D + 120$; for Figure 38, the equation is: $L = 5D + 50$; for Figure 39, the equation is: $L = 2.77D + 72.3$; for Figure 40, the equation is: $L = 1.54D + 59.2$; for Figure 41, the equation is: $L = 0.856D + 124$; and for Figure 42, the equation is: $L = 0.47D + 133$.

Figures 43-48 provide further tabular data, this time for edged or "sharp" hollow microneedles, such as those depicted in Figures 32-34. These edged microneedles are also circular or cylindrical in overall shape, but, as described above, include two longitudinal blades with a relatively sharp edge to aid in penetrating the stratum corneum of the skin. As will be seen as compared to the tables of Figures 37-42, penetrating skin is more easily accomplished using the edged microneedles. As noted hereinabove, an "edged" microneedle is one in which its tip has a radius less than or equal to 0.5 microns.

As before, a table entry of "Y" indicates that a penetration occurs, a table entry of "n" indicates that a penetration does not occur, and a table entry of a diamond-shaped symbol indicates that a penetration of the skin may occur, but is not definite. A dashed line is drawn on Figures 43-48 to indicate the likelihood that entries above the dashed line will not succeed in penetrating the skin, while entries below the line will be successful in such penetration. The lines are indicated by the reference numerals 1022 for Figure 43, 1024 for Figure 44, 1026 for Figure 45, 1028 for Figure 46, 1030 for Figure 47, and 1032

for Figure 48.

Similar equations for these lines can be determined from this data, where again the variable L is equal to the microneedle length and the variable D is equal to the outer diameter of the microneedle. In Figure 43, the approximate equation is: $L = 9D + 30$; in Figure 44, the equation is: $L = 5D$; in Figure 45, the equation is: $L = 2.77D + 11.5$; in Figure 46, the equation is: $L = 1.54D + 56$; in Figure 47, the equation is: $L = 0.856D + 64.4$; and in Figure 48, the equation is: $L = 0.47D + 96.5$.

It can be easily seen from the tabulated data of Figures 37-48 that the greater the separation between microneedles, the more likely that the skin will be penetrated at any given length of microneedle. If relatively small microneedles having an outer diameter of twenty microns are desired for use in a microneedle array, then the tabular data indicates that the microneedle should be at least 100 microns in length, and either 250 or 300 microns separation distance (see Figures 41 and 42). On the other hand, the same 20 micron outer diameter microneedles that include edges (as per Figure 32) will likely penetrate the skin at a needle length of at least 60 microns and a separation of 150 or 200 microns. This is an obvious improvement in microneedle density per unit area of the substrate upon which the microneedle array is mounted, thereby allowing a dramatic increase in the amount of material delivered or extracted through the skin.

Microneedle density is an important factor in dispensing fluids or sampling fluids through the stratum corneum of the skin. This is clearly indicated in the graph of Figure 49, in which the X-axis represents microneedle separation in microns, and the Y-axis represents the transdermal flux of an active fluid such as a niacinamide solution, in units of micrograms per square centimeter per 24 hours of time.

The base or reference line of Figure 49 is represented by the "intact skin" line 1044, which is in essence the transdermal flux rate of normal skin without any microneedles, in the above units of five (5) micrograms per square centimeter per 24 hours time. This base line 1044 is also indicated as being "1X" times a nominal transdermal flux rate. If the stratum corneum layer of human skin is removed, then the transdermal flux rate is increased by a factor of twenty-four (24), and is represented by the line 1042, which indicates approximately one hundred twenty (120) micrograms per square centimeter per

24 hours of transdermal flux flow rate. This line is also referred to as "24X" on Figure 49.

If microneedles are used, the flow rate is variable, as per the curve (or more accurately, the segmented line) at 1040, which at 100 microns of separation provides a 46 times (or 46X) flow rate as compared to the intact skin flow rate of 1X. This flow rate naturally decreases as the microneedle separation increases, since the density of microneedles is proportionate to the square root of separation distance. For example, at a microneedle separation of 400 microns, the transdermal flux rate is only 5 times (5X) the flow rate of intact skin (at 1X).

Figure 49 assumes that the microneedle lengths are sufficiently long and have a sufficient shape to penetrate the skin at the separations listed along the X-axis. Otherwise, the transdermal flux rates will be significantly reduced. However, any microneedle usage that does not actually penetrate the stratum corneum will likely create a certain amount of indents and breaks in the skin, which will provide a certain increase in the transdermal flux rate. For example, if the microneedle array is provided having microneedles of 40 microns in outer diameter and 50 microns in length, it is not likely that microneedle penetration will occur in very many places at virtually any separation. However, there will still be enough indents and breaks in the skin to provide a four times (i.e., 4X) increase in the transdermal flux of a drug or solution such as niacinamide in water. To achieve the results of Figure 49, the microneedle length was 100 microns and its outer diameter was 20 microns. It can be seen from Figure 49 that a microneedle separation of around 170-175 microns will provide results that are equal to the removal of the stratum corneum layer of skin.

Utilizing a passive diffusion model of human skin and microneedle structures, the inventors also provide the chart of Figure 50. The X-axis of Figure 50 represents the microneedle length in microns, while the Y-axis represents the transdermal flux of an active solution, in micrograms per square centimeter per 24 hours time period. The curves on the graph are depicted with respect to a 5% niacinamide solution in water.

The lower curve at 1052 represents a microneedle array in which the needles have a 200 micron separation in a hexagonal pattern. The upper curve at 1050 represents a microneedle array in which the microneedles have a 100 micron separation in a hexagonal pattern. Very useful transdermal flux rates can be provided with microneedle arrays

having a separation of 200 microns at a needle length of 100-110 microns, and an outer diameter of 20 microns. It can be seen from Figure 46 that this range of microneedle lengths and outer diameters lies within a small tolerance of the line 1028 that indicates whether or not microneedle penetration will occur in skin. This table of data on Figure 46 represents edged hollow microneedles, as described above.

Figure 51 provides another measure of usage for microneedles. The X-axis represents microneedle length in microns, while the Y-axis is a ratio of transdermal flux using a solution of niacinamide in water versus skin damage when using the microneedle array. A nominal figure of transdermal flux versus skin damage is provided at the value of one (1) along the Y-axis. The upper curve at 1060 depicts the ratio when microneedles have a 200 micron separation. The lower curve 1062 shows a similar microneedle array having only a 100 micron separation. While the transdermal flux will typically be much greater when the microneedle separation is smaller, also the skin damage will be greater. As can be seen from the curves 1060 and 1062, once the microneedle length exceeds 100 microns, the transdermal flux versus skin damage ratio tends to increase rather sharply. The microneedle outer diameter was 20 microns for the data of Figure 51.

Figure 52 is another graph representing information regarding passive diffusion of fluids using microneedles as compared to the use of microneedles under pressure to increase the transdermal flow. The X-axis is in units of pressure, g's per square centimeter. The Y-axis is the transdermal flux of an active solution in micrograms per square centimeter per 24 hours time period, and the values of this chart are for a 5% solution of niacinamide. In addition, the results of this chart were produced using microneedles of 100 microns length, 20 microns outer diameter, and a separation of 200 microns.

For intact skin, the lowest horizontal line at 1076 indicates a relatively low transdermal flux of the solution to the skin. If the stratum corneum of the skin is removed, this transdermal flux greatly increases to the higher horizontal line at 1072. Another horizontal line at 1074 indicates the transdermal flux rate using microneedles under passive diffusion.

If pressure is applied, then the flow rate changes as the pressure changes. This is indicated by the sloped line 1070. As can be seen, if the pressure is increased by three

orders of magnitude, then the flow rate of the transdermal flux also increases by approximately three orders of magnitude.

Based upon the above information, it is preferred that the outer diameter of circular microneedles (without "sharp" edges) be in the range of 20-100 microns, more preferably about 20-50 microns. In addition, it is preferred that the height (or length) of the microneedles for use with interstitial fluids be in the range of 50-200 microns, more preferably about 100-150 microns; for use with other biological fluids, the preferred length is in the range of 200 microns – 3 mm, and more preferably in the range of 200-400 microns. Finally, it is preferred that the separation between microneedles in the array be in the range of 100-300 microns, more preferably about 100-200 microns. Of course, dimensions outside the above-listed ranges will still be somewhat useful, even for microneedle lengths and separation distances as small as 50 microns, or as large as 1000 microns.

For hollow circular microneedles having edges (e.g., see microneedle 800 in Figure 32), it is preferred that the outer diameter be in the range of 20-100 microns, and more preferably in the range of 20-50 microns. For use with interstitial fluids the length will preferably be in the range of 50-200 microns, more preferably in the range of 80-150 microns; for use with other biological fluids, the length will preferably be in the range of 200 microns – 3 mm, and more preferably in the range of 200-400 microns. Finally, the separation will preferably be in the range of 100-300 microns, more preferably in the range of 100-200 microns.

For solid microneedles of the star-shaped design depicted on Figures 35 and 36, it is preferred that the radius of one of the spokes or edged blades (e.g., blade 910), as indicated by the radius 950 on Figure 36, be preferably in the range of 10-50 microns, and more preferably in the range of 10-15 microns. The length of the solid microneedles will preferably fall in the range of 50-200 microns for use with interstitial fluids, and more preferably in the range of 80-150 microns; for use with other biological fluids, the length will preferably be in the range of 200 microns – 3 mm, and more preferably in the range of 200-400 microns. The separation distance will preferably fall in the range of 100-300 microns, and more preferably in the range of 100-200 microns.

Figures 53A-53E illustrate the steps for preparing a mold to make hollow microneedles, according to the principles of the present invention. The first step is depicted in Figure 53A, in which a substrate 1100 is provided with a top layer of positive photoresist material at 1102. The substrate can be spin coated, or an adhesive can be used to attach the photoresist 1102 to the substrate 1100. The substrate can consist of silicon, silicon-dioxide, plastic, metal, or other suitable compounds. The photoresist material will preferably comprise poly(methylmethacrylate), also known as "PMMA," although other suitable compounds could be used, such as polyoxymethylene (POM), polyalkensulfone (PAS), polymethacrylimide (PMI), and poly(lactide-co-glycolide) (PLG).

In Figure 53B, a mask at 1104 is placed over the photoresist layer 1102, and electromagnetic energy is directed through the mask from a light source, in which the light energy moves in the direction as indicated at 1106 on Figure 53B. The mask 1004 preferably is made of gold metal, and in this instance, the electromagnetic energy comprises x-rays. It will be understood that many different types of photoresist procedures or the like could be used without departing from the principles of the present invention, and for example, high energy nuclear particles might be substituted for electromagnetic energy in some processes.

Figure 53C represents an expose and develop step, in which a chemical compound is used to etch away the portions of the PMMA material that were not protected by the mask 1104 in the prior step at Figure 53B. On Figure 53C, the three-dimensional microneedle shapes begins to become apparent. A pair of hollow microneedle forms are illustrated in Figure 53C at 1110 and 1120. In cross-section, the microneedle form 1110 shows a first wall at 1112, a second wall at 1114, and a hollow area or hole at 1116. Similarly, the microneedle form 1120 comprises a first wall at 1122, a second wall at 1124, and hollow area or hole at 1126.

Both microneedle forms 1110 and 1120 will be of the appropriate length and outer diameter to produce microneedle arrays as recommended hereinabove. The separation between microneedles is depicted by the dimension 1105, and this also will preferably be of a distance as recommended hereinabove.

Figure 53D is a step where the microneedle forms are electroplated with metal. In

the preferred embodiment, this metal at 1130 will comprise nickel. As an optional intermediate step, the substrate 1100 and microneedle forms at 1112, 1114, 1122, and 1124 (which in combination comprise two circular or cylindrical microneedle forms) can be chemically coated to aid in later release before the electroplating takes place.

After the nickel electroplating has achieved the appropriate thickness, the step of detaching this metal form takes place in the step illustrated on Figure 53E. A "reverse contour" mold will now exist, as generally depicted by the reference numeral 1130. Instead of a hollow area or hole, a cylindrical projection now appears at 1132 and 1134 in the metal mold. Similarly, instead of cylindrical or nearly cylindrical projections at 1112, 1114, and 1122, 1124 (as seen on Figures 53C and 53D), there are now hollow cylindrical shapes formed at 1140-1142, and 1144-1146, which represent the areas where the microneedle cylindrical walls will form.

Figures 54A-54C depict the steps of microembossing to form molded microneedles that are hollow, as constructed according to the principles of the present invention. The metal microneedle mold at 1130 is attached to a moveable press ram 1152, to form a structure that will be impressed against a polymer or other plastic material. This moveable structure is indicated by the reference numeral 1150. The polymer or other type of plastic material at 1160 is placed on the surface of a heated plate 1154. The microneedle material preferably will comprise a biocompatible polymer material, although other materials could be used including polycarbon, or even PMMA.

The heated plate 1154 provides sufficient thermal energy to raise the temperature of the biocompatible polymer material at 1160 until it becomes readily deformable. In other words, the polymer material is placed into its "plastic" stage by raising its temperature substantially to its elastic working temperature. The moveable press assembly 1150 is now pressed down toward the heated plate 1154 and against the biocompatible polymer material 1160. It is preferred to accomplish this task within a vacuum to preserve the biocompatibility and sterilization characteristics of the future microneedles.

A cool-down stage is next, as depicted by the final result in Figure 54B. The heated plate 1154 now becomes a cooling plate, and the biocompatible polymer material is cooled to the point where it becomes solid and will not readily deform. The moveable

press ram assembly 1150 is now raised, thereby leaving behind a microneedle array having a substrate at 1162. In the illustrated embodiment of Figure 54B, there are two hollow microneedles at 1170 and 1180, not yet having through-holes in the substrate 1162. The microneedle at 1170 is depicted in cross-section as having a first wall 1172 and a second wall 1174, which are generally cylindrical in shape. These walls surround a hollow area or hole at 1176. Similarly, microneedle 1180 shows a cross-section of a pair of walls at 1182 and 1184, containing a cylindrical hollow area at 1186.

After the cool-down stage, the microneedle array is removed from the plate 1154, thereby leaving behind the structure as illustrated at Figure 54C. The microneedle separation is indicated at the dimension 1165. This dimension is equal to the dimension 1105 depicted on Figure 53C.

It will be understood that other types of plastic forming processes can be used than embossing. In fact, virtually all types of molding or micromolding processes can be utilized. Embossing is one subset of these types of moldings, and injection molding is a second subset, which was described hereinabove for other microneedle shapes.

The above structure depicted in Figure 54C could be used as the "final" product for certain uses with skin. This structure consists of substrate 1162 and two hollow microneedles 1170 and 1180, in which the hollow cavities 1176 and 1186 each form a small cup-like volume that does not protrude completely through the substrate 1162. This structure could be used for drug delivery by filling the cup-like hollow cavities 1176 and 1186 with a drug active that can slowly leach out into biological systems.

Figures 54D-54F illustrate various methods of forming chambers beneath the microneedle array, and forming through-holes. In Figure 54D, a hollow chamber at 1190 is formed on the opposite side of the substrate, thereby forming a microneedle array structure 1192 that contains hollow microneedles 1170 and 1180, and a chamber that can hold some type of fluid. This chamber can be formed by micromachining, or perhaps by an oxygen plasma etching process. Other methodologies could be used without departing from the principles of the present invention.

In Figure 54E, a laser light source is used to finish the "drilling" process to make through-holes that are concentric or otherwise centered along the hollow microneedles

1170 and 1180. On Figure 54E, a laser light source is used to burn away some of the substrate material along the lines at 1194 and 1196. The final result is shown at Figure 54F, in which a final microneedle array 1198 is illustrated showing through-holes from the chamber 1190 to the top of the microneedles, in which the microneedle openings 1176 and 1186 are aligned with the laser light burned holes at 1195 and 1197, respectively.

Figures 55A-55F illustrate an alternative methodology for constructing hollow plastic microneedles. Starting with a laminate material at 1200 and a biocompatible polymer at 1202, these materials are joined along a planar surface at the line 1204 on Figure 55A. This joining can be performed by an adhesive process, or other temporary mechanical means.

A mold 1210 is now provided, which preferably will be made of a metallic or other suitable material. In Figure 55B, the biocompatible polymers are placed on a heated plate 1212, and the mold 1210 is placed upon a moveable press ram. After the mold has been pressed into the biocompatible polymers, the ram press is removed and the material is cooled, thereby arriving at a structure illustrated in Figure 55C in which holes 1224, 1226, and 1228 are formed all the way through the upper layer, now designated as 1220. These holes also continue part-way into the lower layer at 1222.

The laminate materials that were earlier glued together are now detached from one another. This now provides a film structure 1220 that has the through-holes 1224, 1226, and 1228, and is illustrated in Figure 55D. This film layer 1220 is now placed upon a heated plate 1230. A mold structure 1280 is now provided and will be pressed against film layer 1220 after the film layer 1220 has been heated to its plastic stage. On Figure 55E, the cylindrical projections 1282, 1284, and 1286 are used to create the through-holes for three hollow microneedles.

In an alternative configuration, the cylindrical projections 1282, 1284, and 1286 can be somewhat shortened so that they rest against the planar top surface of the heated plate 1230, i.e., along the horizontal (on Figure 55E) line 1235. The heated plate 1230, in this alternative configuration, would be substantially flat along its top surface at 1235, such that the openings 1232, 1234, and 1236 would be filled.

After the pressing process has occurred and the material 1220 is cooled (by plate

1230) to the point where it becomes solidified, the mold 1280 is removed and a new structure at 1240 is formed and removed from the plate 1230. This is illustrated in Figure 55F. This new structure 1240 represents a microneedle array having three hollow cylindrical microneedles at 1242, 1252, and 1262. These microneedles have hollow through-holes as illustrated at 1244, 1254, and 1264, respectively.

Another use for the microneedles of the present invention is to include a sensing capability by some type of optical means with a plastic microneedle array structure that is constructed of a substantially transparent material. This could be used with both hollow and solid microneedles, although it is preferred that solid microneedles be used to prevent contamination of the light source mechanism that is being utilized for this sensing capability. In Figure 56, a microneedle array structure 1300 is depicted as having a substrate 1302, and three microneedles at 1310, 1320, and 1330. The upper areas of these microneedles near their tips are coated with a chemical material that aids in detecting a chemical or other biological process. This chemical coating is indicated on the three microneedles at 1312, 1322, and 1332.

Once the microneedle array 1300 has been placed into the skin, a light source is used to provide electromagnetic energy in the direction indicated by the arrows 1350. It is preferred that the light source be some type of laser source, so that the electromagnetic energy is collimated. The chemical coating at 1312, 1322, and 1332 will be of a type that will either change color or change its light passing characteristics when in contact with the target fluid or biological materials. In this methodology, the laser light that is reflected back toward the optical energy source will either be reduced in intensity, as compared to before any chemical changes were noted at the ends of the microneedles, or will have a color variation.

Another use for this configuration is to provide optical energy directly into portions of skin that can be directly affected or stimulated by certain frequencies of light. In this instance, the laser light may directly provide either optical or thermal energy into skin tissue, or could provide a methodology for transferring such energy into muscle tissue at certain locations in an animal body.

Alternatively, the sensors can be integrated with the microneedle-array by layering the sensor components on the face of the device containing the protrusions that will perforate the skin. One or more layers can be used depending upon the complexity of the detection process. Simple conductivity measurements for analytes like sodium ions can be made with only one conductive layer of a biocompatible material, such as the layer 1312 on Figure 56A, or a layer 1372 on Figure 56B.

More complex analyses (e.g., glucose) are accomplished by using several layers of sensing materials. To prepare an enzyme electrode, a biocompatible prepolymer doped with an enzyme, an enzyme modified with a polymerizable group, or an enzyme modified with a group that can be tethered or adsorbed to the electroconductive surface is coated on top of the electrically conductive polymer and is polymerized using a curing agent or an energy source such as light, or heat as necessary. This is illustrated in Figure 56B where the coating constitutes an enzyme layer that is depicted at 1374. The electrically conductive layer is depicted at 1372. A single microneedle structure 1370 is illustrated in Figure 56B as a longitudinal element protruding from a substrate 1360, however, it will be understood that many such longitudinal elements can be constructed on the substrate 1360 to create a microneedle array (similar to, e.g., the microneedles 1310, 1320, and 1330 on Figure 56A).

The enzyme film can also be coated with additional layers of biocompatible polymers (as depicted at 1376) that can be employed to protect the sensor components from leaching, reactions with biological entities, or to regulate the access of analytes to the enzyme layer. As depicted in Figure 56B, the electrically conductive layer 1372, enzyme layer 1374, and "top" polymer layer 1376 are deposited on virtually the entire surface of the microneedle array, except for an portion at the end of the substrate structure, as generally depicted by the reference numeral 1365. The side walls of a microneedle array comprising multiple microneedle devices such as the microneedle structure 1370 are not completely coated with the enzyme layer 1374 or second polymer layer 1376, because those areas will be used for electrical contact with an electrochemical analysis circuit. Therefore, only the electrically conductive layer 1372 is deposited throughout the upper

surface of the substrate 1360, including the portions near the left (on Figure 56B) hand end, at the numeral 1365.

These sensor component layers 1372, 1374, 1376 can be deposited on microneedles (e.g., microneedle 1370) by dipping the microneedle devices in the appropriate chemical reagents, spin-coating techniques, electro deposition, stamping, deposition of dry powders, and similar processes known by those skillful in the art. The left-end portion near 1365 is preferably masked during the deposition procedures for the enzyme layer or second polymer layer, thereby leaving exposed the electrically conductive layer 1372 in this region.

The first conductive layer 1372 deposited on the microneedles can consist of many available materials; metals are preferred and include: Au, Cr, Ti, Pt, Ag, Cu. Conductive polymer mixtures such as 7,7,8,8-tetracyanoquinodimethane with tetrathiafulvalene or N-methylphenazinium can also be used. Furthermore, conductive polymers such as polyacetylene, polythiophene, polyparaphenylene, and polyphenylene vinylene and polyaniline can be used.

The enzyme coating can be entrapped in any one of the following polymers or copolymer mixtures in the second layer at 1374: glutaraldehyde, poly(ethylene glycol) dicyclyd ether and poly[(1-vinylimidazole) osmium (4,4'dimethyl bipyridine)₂Cl], poly N-methylpyrrole, poly [(vinyl pyridine) Os(bipyridine)₂Cl], cyclodextrin polymers, and gelatin.

The outer biocompatible protection layer at 1376 can include: silicones, fluorinated-ethylene propylene, nafion, cellulose, poly(vinylpyridine) acetate, aziridine, polyurethanes, epoxies, fluorocarbons, acrylics, parylene, and polyimides.

Another use for this configuration is to provide electrical energy directly into portions of skin that can be directly affected or stimulated by a small electrical current. In this instance, the electricity is conducted via the conductive layer 1372. If it is desirable to provide electrical current directly at the tips of the microneedles, then the enzyme layer 1374 and protective polymer layer 1376 can be eliminated from the manufacturing process, leaving only the electrically conductive layer 1372 covering the entire substrate 1360 and microneedle structure at 1370. In this manner, electrical energy may be directly provided

into skin tissue, or could ultimately be transferred into muscle tissue at certain locations in an animal body.

Figures 57A and 57B illustrate a refinement of the embossing process that was earlier described in relation to Figures 54A-54C. In Figure 57A, the microneedle substrate at 1400 has been deformed by a metal (or other type of material) mold at 1410. A single hollow microneedle structure is being formed in Figure 57A, as indicated by the cross-section cylindrical wall at 1402 and 1404. As the substrate material 1400 is cooled, shear forces are generated during the de-molding procedure which occurs when the mold 1410 is removed from the upper surface of the substrate 1400. These shear forces will mainly occur along the inner surfaces of the walls 1402 and 1404, which indicate the inner diameter of the hollow microneedle near its tip.

The amount of shear forces can be controlled by the cool-down temperature and timing as to when the mold 1410 is released. If the shear force is maintained at a sufficient magnitude, the final structure will not have a perfectly flat surface along the top of the microneedle, but instead will have a shape similar to that of the microneedle 1420 depicted in Figure 57B. In this microneedle 1420, the upper surface of the microneedle has sharp points at 1422 and 1424, and a rather arcuate shape along two of its semi-circular edges at 1426. This shape also can be parabolic or elliptical in nature, and the important aspect of this shape is to provide sharper edges at the points 1422 and 1424. This is an alternative methodology for forming hollow circular microneedles that can more easily penetrate the stratum corneum of skin, and may not require the edged blades of the microneedle structures depicted in Figure 32.

The star-shaped solid microneedle structures can also be created using a molding process similar to that depicted in Figures 53A-53E, and 54A-54C. Of course, the solid microneedles will not require through-holes that are in alignment with the center of each microneedle, but will instead require through-holes in the substrate material at locations that are substantially proximal to the pair of blade structures near the top surface of the substrate.

It will be understood that all types of molding or casting procedures could be utilized in conjunction with the present invention, so long as these molding procedures can

be utilized to create the very small structures required by the microneedles of the present invention. Furthermore, semiconductor fabrication techniques can be used to create the structures illustrated on Figures 32-36, using processes that were described hereinabove in reference to Figures 18-22. Certainly fluid reservoirs can be constructed for use with the microneedle structures of Figures 32-36, and furthermore various methods of use can be utilized with these microneedle structures, such as electrophoresis or ultrasound.

Another use for arrays of microneedles is to apply semi-permanent or permanent markings to skin, or to apply semi-permanent subcutaneous makeup to skin. With regard to marking skin, the microneedle arrays could be used to apply identifications or other graphics, in a manner that is similar to applying tattoos. If the microneedles are made to a particular range of lengths, and will therefore not enter into the dermal layer of the skin, then these markings will be applied without any pain, as opposed to standard tattoo applications.

One very useful situation for applying markings using the microneedle arrays of the present invention is to assist patient identification in hospitals and clinics by use of a permanent or semi-permanent marking, including the use of a special ink that would be invisible at normal light wavelengths, but instead would be visible using fluorescent light, for example, so that it could be discerned only with a special reader. Regardless of the exact light wavelengths that are visible with a particular ink used in the present invention, it is preferred that ink having particles of a certain minimum size be used for semi-permanent markings, so that the particles will not diffuse too far into the skin. Such diffusion is not desirable unless a permanent marking is desired. A dye may be used instead of ink; however, since a dye has smaller molecules, it would be much more likely to diffuse further into the skin, i.e., into the dermal layer (and possibly beyond) even when the microneedles themselves only penetrate into the epidermis.

Any type of ink or pigments could be used if one or more colors are desired, so long as the particles that make up the ink or pigment coloration are of a minimum size. Iron oxide particles, chromium oxide particles, or titanium oxide particles are examples of ink or pigment materials that could be used in an ink that could be dispensed through the microneedles into the epidermis of skin. If these particles are sufficiently large, they would

not likely go through the entire epidermis into the dermis layer, but would instead lodge in the epidermis. Since the epidermis layer is renewable, the marking will disappear from the skin after a time period. Therefore, a semi-permanent mark or tattoo can be easily applied using the microneedle arrays of the present invention.

When using intracutaneous microneedles, the ink will remain in the epidermis layer and will not penetrate into the dermis layer, thereby reducing the risk of infection and of allergic response. Furthermore, no pain will be suffered by the person having the marking applied, and the danger of infection is much reduced.

The overall structure of the microneedle array could be supplied in the form of a microneedle "patch" that is attached to the skin at the time the ink is to be transferred from the microneedles to the epidermis. The microneedles each deliver an exact predetermined quantity of ink that will produce a marking or tattoo of very high quality. If a separation distance between the microneedles is maintained at about 100-300 microns for an array that is arranged in a hexagonal pattern, this will provide very high resolution for the purpose of tattooing, and this is much better than the spatial resolution that can be attained by conventional methods of applying tattoos. If the markings or tattoos are to be of different colors, then a precise pattern of ink colors can be supplied to the appropriate microneedles, and therefore, the color resolution of the final marking or tattoo should be much better than for any conventional tattoos.

The microneedle patch could be made disposable, thereby making this methodology very safe and convenient. The user does not have to be concerned about the quality of the final marking, since the marking or tattoo is preset in the microneedle array itself.

There may be situations where it is desired to produce permanent markings, including fluorescent tattoos that are invisible to normal light wavelengths. This permanent type of marking can be assured by extending the microneedle length so that it will definitely deliver ink into the dermis layer. This will provide a long-lasting tattoo, and this methodology will keep most of the benefits of the semi-permanent marking methodology described hereinabove. Permanent fluorescent tattoos could be used for permanent identification of patient blood type, allergies, and other important medical

conditions. Moreover, permanent tattooing could be used for invisible identification of certain persons, such as military personnel or convicted criminals.

It is still preferred to use inks with pigments as opposed to dyes even when preparing permanent markings using the microneedle patch of the present invention. The particles that are used to produce the pigments and inks are superior to dyes, since the particles will much more likely stay in place, due to a low diffusion coefficient in the skin for particles of a "larger" size. As described above, a dye has much smaller molecules (particularly as compared to solid particles) and will be much more likely to diffuse further into the skin, which could mean that it could diffuse in a plane that basically is parallel to the surface of the skin, thereby blurring or otherwise deforming the pattern of the marking.

The use of visible ink to make permanent markings is more preferable when marking animals or pets for identification. In this case, the preset designs made by the microneedle patch can be made as alphanumeric symbols to be applied to the skin of the animal in a series of symbols, in order to obtain the desired identification number or lettering scheme. In this situation, the microneedles of the patch will preferably be made of a sufficient length to penetrate into the dermis layer of the skin of the animal.

One arrangement that could be useful for applying a marking to skin is a microneedle marking apparatus or microneedle patch that includes an array of microneedles and a housing that holds not only the microneedles in their appropriate locations, but also contains an electrochemical gas generator with a button-cell battery. The microneedle array is filled with marking inks, of either a single color, or of separate and different colors, as desired. If a single color is to be used, then a single reservoir can be used to source ink to each one of the microneedles that is to dispense ink into the skin. On the other hand, if different colors are to be used, then each appropriate microneedle will be required to have its own very small reservoir of appropriate ink color, which will be dispensed at the appropriate time into the skin.

In situations where the microneedles are to dispense different colors of ink in a single microneedle array pattern, then the microneedle patch will provide an array of hollow microneedles in which a flexible membrane is attached to the base of each microneedle that is to dispense ink. Individual reservoirs are thereby formed beneath the

multiple flexible membranes, and these reservoirs are filled with the specific colored ink that will form the desired marking. The far or distal ends (i.e., the tips of the microneedles that will penetrate into the skin) for the particular microneedles that are not going to dispense any ink at all can be sealed by use of glue or some other deposition of material into the end of the microneedle, or by using heat to seal the microneedle end along with the attachment of a layer of plastic film at the end points.

On the other hand, if a monochrome marking is desired, then a single large reservoir can be formed with a large flexible membrane that is attached to the bottom structure of the microneedle patch that is in contact with the base end of the microneedles (i.e., the end of the microneedles that is distal from the skin upon application of the marking).

In both monochrome and multi-color markings, the microneedle patch structure is preferably made using a base structure having an internal air or gas volume that encloses the flexible membranes that are described above. Within this internal volume or cavity, the electrochemical gas generator is placed, with electrical leads that are attached to an actuation mechanism and the button-cell battery. Once actuated, electrical current is supplied to the electrochemical gas generator, at which time a gas is released to create pressure within the internal cavity, which will then increase pressure on the surface of the membrane surface (or membrane surfaces in the case of a multi-color microneedle array). When the gas pressure builds to a sufficient amount, the membrane(s) will be deformed to squeeze the ink through the hollow microneedles into the skin. Of course, the plastic film that was previously covering the external tips of the microneedles would first have to be removed before the microneedle patch is applied to the skin.

In a preferred microneedle patch structure, the microneedles themselves are constructed of high strength plastic, such as nylon, by use of micromolding techniques such as LIGA or LIGA-like processes, including hot embossing, or hot embossing with silicon or silicon carbide molds that are microfabricated by conventional micromachining. Once the array of microneedles has been formed, a pattern can be created by selectively plugging certain microneedles using glue or heat, or adding or depositing material into the microneedle hollow spaces, thereby preventing any type of ink or dye from flowing

through the hollow opening of the particular microneedle upon application onto skin. Of course, the microneedles that are to dispense ink will not be glued or plugged shut.

An optional methodology for manufacturing the microneedle patches is to create a patterned array upon initial manufacturing of the microneedle array. This would create from the beginning a certain pattern that will not be changeable, and could be useful for high-volume markings. The alternative methodology is to create an entire microneedle array of hollow microneedles that all remain open until a later time, when it is actually time to determine what the precise pattern shall be for a particular microneedle patch.

As discussed hereinabove, a preferred microneedle patch would be disposable, however, it certainly could be made reusable. The microneedles themselves could be made of other materials besides plastics, and for example could be made of metal, or could have a metal outer surface, and furthermore could be made of a silicon or a silicon dioxide material using semiconductor fabrication techniques. One preferred material for use as the electrochemical gas generator is a zinc oxide compound, and when electrical current is applied to this material it will release oxygen to cause a pressure increase within the internal cavity.

Referring now to Figure 58, a microneedle patch is illustrated in an elevational cross-section view in which the patch itself is generally designated by the reference numeral 1500. An array of individual microneedles that are hollow is indicated at the reference numerals 1510, and they are illustrated as penetrating through a stratum corneum layer 540 and into an epidermal layer 542. The microneedles are of a length that do not penetrate to the dermis layer at 544. Of course, for certain applications it may be desirable to increase the length of the microneedles 1510 so that they actually purposefully penetrate into the dermis layer 544.

The microneedle patch 1500 has an internal volume or cavity that is generally designated by the reference numeral 1520. Within this cavity are multiple flexible membranes at 1514, and within each of these flexible membranes is (potentially) a different color ink, as indicated at 1512. Of course, the same color ink could be used in many if not all of these microneedles 1510, however, the structure illustrated in Figure 58 is specially designed for multi-color patterns to create markings on skin of different colors. An

electrochemical generator is also located within the cavity 1520, and the electrochemical gas generator is designated by the reference numeral 1522. This gas generator is activated and powered by a battery that is illustrated in schematic format at 1524 on Figure 58. As described hereinabove, once the gas generator 1522 is activated, it will release oxygen or some other gas that will increase the pressure within the cavity 1520, thereby forcing the flexible membranes 1514 to deform downward as viewed on Figure 58. This action will squeeze the ink out of the small reservoirs at 1512 and through the hollow internal spaces of the microneedles 1510 into the epidermis 542.

Figure 59 is another elevational view in cross-section of the top layers of skin 540, 542, and 544, as before. However, the ink that was previously dispensed by the microneedles 1510 has now been deposited within the epidermis and stratum corneum layers, which has produced tiny pockets of colored ink, as indicated at the reference numeral 1530. If the ink, or pigments in the ink, are comprised of colored particles, then these pockets 1530 will remain essentially where they started in the skin, and will not diffuse either horizontally or vertically in the view of Figure 59. This produces a high-definition marking or tattoo, and will also assure that the marking/tattoo will eventually disappear from the skin, since the epidermis is renewable.

Figure 60 is another elevational view in cross-section of an alternative microneedle patch, generally designated by the reference numeral 1550, that has individual microneedles at 1510 with individual membranes at 1514 which are accessible to being directly contacted by the human user. In Figure 60, a person's finger is designated at 1540, and the finger can be used to directly press against the upper surface of the membranes 1514.

When the person presses against the membranes 1514, the ink within the small reservoirs at 1512 will be squeezed through the hollow openings in the microneedles 1510 into the skin, specifically through the stratum corneum 540 and into the epidermis 542. In the embodiment illustrated in Figure 60, the microneedles 1510 are not of sufficient length to reach into the dermis at 544, although the microneedles could certainly be made longer if it were desirable to directly penetrate into the dermis.

Since the microneedles are quite small with respect to a human finger, they will be

pressed in large numbers by even the smallest portion of a person's finger pressing against what may be perceived as only a small portion of the microneedle array. Of course, if a tattoo or specific marking is to be impressed into the skin, then it would be recommended that the person press his or her finger against the entire microneedle array, even though it may not be possible to do that in a single pressing operation, depending upon the physical length and width of the array 1550 as it is being placed into contact with the skin. At the scale of Figure 60, the eight (8) microneedles 1510 that are illustrated in a single row only cover a center-to-center total distance of about 0.7 mm, and certainly they would all be depressed or squeezed at one time if a person were to place their finger over these particular microneedle placements.

Figure 61 is another alternative embodiment shown in an elevational cross-section view, in which a microneedle patch designated at the reference numeral 1560 includes "double-sided" microneedles. These double-sided microneedles are indicated at the reference numerals 1570, and preferably would have approximately the same separation distance (i.e. spacing) between centers of the hollow microneedles. Therefore, the human finger at 1540 would still depress virtually all of the upper membrane surfaces at 1514, thereby squeezing the ink out of all of the tiny reservoirs at 1512 through all of the hollow microneedles at 1570.

As in Figure 60, the microneedles 1570 are shown as having a length that would allow the ink to penetrate through the stratum corneum at 540 and into the epidermis at 542. Being of this length, the microneedles 1570 would not directly deposit ink into the dermis layer at 544, although these microneedles could certainly be made longer so that they would directly penetrate into that dermis layer.

The illustrated embodiments of both Figures 60 and 61 are depicted as having individual membranes 1514 at the base end of the microneedles 1510 or 1570, respectively. This would allow for different colors of ink or different pigment colors in the ink (or other type of solution or fluid) to be placed within the tiny reservoirs at 1512, thereby allowing a multicolor marking or tattoo to be placed onto the skin by this microneedle array or patch.

In Figure 60, the microneedle patch 1550 preferably would be shipped from the

factory with a plastic tape or other membrane (not shown on Figure 60) covering the bottom tips of the microneedles 1510, similar to that illustrated in Figure 62 where tape 1602 is used to protect the microneedle tips. The use of such tape will protect the fluids 1512 within the pockets formed by the individual membranes 1514 from outside contamination. This could be very important if the fluids consist of a biological active, as discussed in greater detail hereinbelow. The use of the tape also prevents the fluids from prematurely leaking out of the pockets through the hollow microneedles 1510.

In Figure 61, the double-sided microneedles 1570 are specifically designed to penetrate in both directions, i.e., both upward and downward as seen in Figure 61. The downward penetration is, of course, to penetrate the upper layers of skin, specifically the stratum corneum and into the epidermis. However, the upward penetration is to pierce the membrane-covered pockets of fluid 1512 when it is time to dispense that fluid. In the microneedle patch 1560, the fluid-containing pockets 1512 are formed with both a top membrane at 1514 and a bottom membrane at 1516. This completely seals the fluid at 1512 within the individual pockets until needed. In fact, the fluid-filled membranes can be manufactured entirely separate from the microneedles 1570, in two completely unrelated processes, and the separate sub-assemblies are later matched in a final assembly line before shipment from the factory. For example, the microneedles 1570 could be formed by microembossing or by semiconductor fabrication techniques, as described hereinabove, while the fluid-filled membranes 1512 could be formed by completely different processes as a plastic-wrap structure.

When it is time to dispense the fluid from within the pockets at 1512, the microneedles 1570 penetrate into skin using the lower (on Figure 61) portion of the microneedles at reference numeral 1574. Simultaneously, the microneedles 1570 penetrate into the fluid-filled pockets at 1512 using the upper (on Figure 61) portion of the microneedles at reference numeral 1572. This upper portion 1572 of each microneedle 1570 is designed to pierce and penetrate the bottom membrane 1516 of a corresponding fluid-filled pocket 1512, and only then does the fluid become exposed to any type of outside contaminants. Of course, the fluid is simultaneously being squeezed from above by tactile pressure on the upper flexible membrane 1514 of each fluid-filled pocket at 1512,

and therefore, there is no substantial chance for any contaminants to enter through the microneedles 1570 (since the fluid is being forced through the hollow microneedle 1570 in the downward direction as seen on Figure 61).

Figure 62 is an elevational view in cross-section of a microneedle patch apparatus that is generally designated by the reference numeral 1600. Microneedle patch 1600 includes a very large number of individual microneedles at 1610 that are constructed in an array format, preferably with a spacing that is approximately one hundred microns from center-to-center of the individual microneedles 1610. This array pattern could be a hexagonal pattern, or any other type of geometric pattern that makes sense to the manufacturer or to the user. The microneedles 1610 preferably are hollow in this physical structure, and have a common reservoir of ink that is indicated at 1612.

The microneedle patch 1600 is generally constructed of a housing that includes a bottom substrate at 1606 that supports and holds the microneedle array in place, and also provides a surface for a strip of double-sided tape or adhesive hydrogel placed around the perimeter of the microneedle array substrate 1606 (i.e., on both the left and right ends as viewed on Figure 62), as indicated at the reference numeral 1604. This double-sided tape (or double-stick tape) 1604 is used to temporarily hold in place the microneedle patch apparatus 1600 on the skin during its operation as well as to hold a thin layer of protective film 1602, that will protect the microneedles 1610 after manufacturing and during shipment, up until the time of actual use. When it is time to use the microneedle patch 1600, the protective film 1602 can be easily removed by hand from the two pieces of tape 1604, thereby uncovering the distal end of the individual microneedle 1610, for placement on and penetration into the skin.

The microneedle patch housing also encloses the reservoir 1612 which has a flexible membrane at 1614 to hold the liquid ink, or dye, or other useful substance within the desired spaces within the cavity that is designated by the reference numeral 1620. The upper wall or ceiling of the cavity 1620 is mainly formed by an electrochemical gas generator that is designated by the reference numeral 1622. As described hereinabove, electrochemical gas generator 1622 will, upon activation, release a gas that will pressurize the air spaces within the cavity 1620, which will tend to force the flexible membrane 1614

down (as viewed on Figure 62), thereby forcing the ink or other liquid substance at 1612 to flow through the hollow microneedles 1610.

On Figure 62, a button-type battery is indicated at 1624, and some electrical wires are indicated at 1626, which provide a pathway for electrical current from the battery to flow into the electrochemical gas generator 1622. It is preferred that some type of activation device, such as a bubble switch or other type of membrane pushbutton switch (not shown) be utilized to actuate the electrochemical gas generator 1622. Once activated, the gas generator can be allowed to automatically proceed and dispense all of the usable portion of the liquid substance (e.g., ink) through the microneedles 1610, even if the pushbutton switch or other type of membrane switch becomes non-activated by the human user. In other words, once the pushbutton switch or other type of switch is activated, it could be "latched in" by simple electronic logic so that the gas generator will run continuously until the ink is dispensed.

Alternatively, it may be desirable to allow the gas generator to only run for small time intervals, in which case the pushbutton switch should directly control the electrical current flowing from the battery 1614 into the electrochemical gas generator 1622 such that if the pushbutton switch or other actuation device is not being actuated by the human user's finger, then the gas generator 1622 will stop generating gas (even if some ink or other fluid still remains within the reservoir cavity 1620).

Figure 63 is another elevational view in cross-section of the microneedle patch 1600 after its protective film 1602 has been removed from the distal end of the microneedles 1610 and the double-sided tape 1604. In Figure 63, the microneedle patch has been positioned on the surface of some skin, which is indicated at the reference numeral 1630. In the view of Figure 63, the electrochemical gas generator 1622 has not yet been activated, and the full supply of liquid substance at 1612 still remains within the reservoir cavity at 1620. This can be easily discerned by the fact that the flexible membrane at 1614 still retains a convex shape as seen from above on Figure 63. This situation will, of course, change as soon as the electrochemical gas generator 1622 is activated and current is supplied from the battery 1624.

Figure 64 is another elevational view in cross-section of the microneedle patch

1600 as it is positioned on the skin 1630. In Figure 64, the ink (or other liquid substance) has been almost entirely dispensed through the microneedles 1610 and into the skin. The ink (or other liquid substance) is depicted in Figure 64 as now comprising multiple small patches of ink or liquid, as generally depicted at the spots 1632 on this figure. The ink (or other liquid substance) does not uniformly flow through every single microneedle 1610 within the array that is provided by the microneedle patch structure 1600, but instead only flows through a set of predetermined microneedles that were not closed up, sealed, or plugged by some methodology during manufacturing, thereby rendering a specific pattern of markings (or tattoos, if desired) in the skin upper layers, as was described hereinabove.

In Figure 64, the flexible membrane 1614 is depicted as having a concave shape as viewed from above. This indicates that the gas generator 1622 has been activated, and the air pressure within the cavity 1620 has increased to a sufficient magnitude to force the ink or other liquid substance to flow through the microneedles 1610 into the skin 1630. The pressure required to force the ink into the skin may be considerable, since the skin membranes have a certain internal pressure that would certainly resist any particular new liquid or other substance in solution to be forced through the stratum corneum into the epidermis. This additional pressure that must be produced by the gas generator 1622 is, of course, an important design parameter.

Figure 65 is an elevational cross-section view of another microneedle patch apparatus that is generally designated by the reference numeral 1650. The microneedle patch 1650 has a similar structure in some respects to the microneedle patch 1600 that was depicted in Figures 62-64. However, microneedle patch 1650 also has some important differences, the main difference of which is that there is no electrochemical gas generator and no battery or other electrical power supply required. In addition, there also is no internal cavity or chamber that can be pressurized. Instead, the flexible membrane 1614 is exposed to direct contact by a human finger or some other type of tactile device.

The bottom portion (as viewed in Figure 65) of microneedle patch 1650 is virtually identical to the bottom portion of the microneedle patch 1600. There is a bottom wall at 1606 that provides the substrate structure for the array of microneedles, in which the microneedles are indicated at 1610. In addition, the bottom portion also includes some

double-sided tape or adhesive hydrogel at 1604 that is used to hold the microneedle patch apparatus 1650 on the skin during its operation as well as to hold a protective film (not shown on Figure 65) in place after manufacture of the microneedle patch 1650 and during shipment, until the time of actual use. Since the microneedle patch 1650 is illustrated in Figure 65 as being placed upon the upper surface of skin (at 1630), this protective film or tape would already have been removed.

The flexible membrane 1614 is illustrated in Figure 65 as having a convex shape as seen from above in this view. Therefore, a large quantity of ink or other liquid substance is contained below that membrane 1614, as illustrated at 1612 on Figure 65. The ink (or other liquid substance) 1612 will remain in this position until pressure or some other type of force is exerted against the membrane 1614. Such pressure or force can easily be applied by use of a human finger, as depicted at the reference numeral 1640.

Figure 66 shows the result of the use of force provided by a human finger at 1640 against the microneedle patch 1650. Figure 66 is another elevational cross-sectional view, in which the microneedle patch 1650 remains atop a layer of skin at 1630. The finger 1640 has been pushed as far down as it can in this illustration, and therefore the flexible membrane 1614 has now been forced into a concave shape as seen from above in this view. When this occurs, virtually all of the ink (or other liquid substance) at 1612 has been forced through the hollow openings of the individual microneedles 1610 which are available to allow liquid to flow therethrough. Of course, certain of the microneedles 1610 in the microneedle array are closed by a plug or some other method of sealing, and therefore, not every individual microneedle 1610 will have any type of ink or other liquid substance flowing through its hollow center.

On Figure 66, the end result is a series of small ink spots that are depicted by the reference numeral 1632. These small spots comprise the markings that are predetermined by the microneedle array pattern that determines which hollow openings of the microneedles 1610 will remain open to allow the ink (or other fluid) to flow therethrough. Whether or not these small ink patterns or spots 1632 are placed into the epidermis layer only, or whether they penetrate further into the actual dermis layer, is a function of the length of the individual microneedles 1610. Depending upon whether or not the marking

is to be permanent or semi-permanent, then the microneedle patch 1650 will be constructed accordingly.

It will be understood that all manners of size and shape of microneedles can be used to dispense ink (or other fluid) in patterns or spots as described hereinabove, without departing from the principles of the present invention. While hollow microneedles are preferred for these applications, solid microneedles could instead be used, whereby the ink (or other fluid) patterns would be determined by predetermined hole placement in the substrate (as illustrated, for example, in Figures 24, 26, 29, and 35-36 where holes are placed adjacent to solid microneedles of various shapes).

The structures that have been described hereinabove in reference to Figures 58-66 are useful not only for marking or tattooing skin, but also for delivering specific compounds or actives into the skin for other useful purposes. For example, cosmetic compounds or nutrients, or various skin structure modifiers can be delivered subcutaneously without having to visit a cosmetic surgery clinic and without having to pay the typically very high fees for some type of skin enhancement service. In addition, some type of color cosmetics could also be delivered subcutaneously to provide long-term benefits for the skin, and even makeup or lipstick-type coloring compounds can be delivered by use of the microneedle patches described hereinabove.

Conventional makeup provides two major benefits for a consumer: (1) improvement of the skin structure, and (2) enhancement of skin color. The benefits of conventional makeup are normally active for only a short period of time, for example, a single day. People desiring to have longer term benefits may choose to undergo cosmetic surgery to enhance their appearance. Such cosmetic surgery procedures are very expensive, and such costs can be prohibitive to many people.

When using the microneedle array structures in the form of a microneedle patch as described hereinabove, color cosmetics can be subcutaneously delivered into the skin to provide long-term benefits. If these color cosmetics are delivered into the epidermis, they would remain in place for at least one or two months, and therefore, would reduce the number of times an application is needed to once every one or two months, as compared to thirty or sixty times during the same time period if conventional cosmetics are applied

once per day. Since the epidermis is renewable, the color makeup or color cosmetics that are delivered using the microneedle patch of the present invention would eventually wear out, since the epidermis is renewable.

The microneedle patch of the present invention provides a method for injecting color cosmetics and skin structure improvement ingredients subcutaneously by use of an intraepidermal microneedle array. The epidermis is a renewable layer of skin located beneath the stratum corneum (which is a dense layer of high-density cells), and the intraepidermal injection allows large molecules to be delivered across the stratum corneum. By use of this intraepidermal injection, the delivered molecules will automatically be removed from the epidermis by natural skin removal, after 1-3 months for most people.

Therefore, the delivered color pigment or dye, or skin structure support actives (such as polymers) will remain in the epidermis for only a finite time (e.g., 1-3 months), and then will be expunged from the body. This allows a person to change their "look" according to changes in fashion and style, which typically change every season. By use of the microneedle patch of the present invention, a person will nevertheless save large amounts of time by eliminating the need of applying makeup every single day. Moreover, the use of the microneedle patch of the present invention also provides an additional possibility of creating high definition color patterns on the skin that cannot be achieved with conventional color cosmetics.

The intraepidermal injection that can be achieved by the microneedle patch of the present invention does not involve contact with blood, and is not life threatening. Therefore, this intraepidermal injection may be performed by an individual consumer instead of by trained medical personnel. While the intraepidermal makeup may be slightly more expensive than regular color makeup available today, it will nevertheless be much less expensive than cosmetic surgery.

The microneedle patch structure that can deliver cosmetics or nutrients or skin structure improvement ingredients will preferably be very similar or identical to the microneedle patch structures described hereinabove that were able to be used in creating markings or tattoos on skin. There may be some difference in the actual size of the

microneedles in the array, or in the pressures used to dispense the various materials, especially if certain cosmetic compounds or nutrients have a greater or lesser viscosity as compared to inks or dyes used in creating markings or tattoos. The overall structure would nevertheless be similar, and preferably will include a microneedle array that includes either individual membranes or one large membrane to dispense the cosmetic compounds, nutrients, or skin structure improvement ingredients.

If multiple colors are desired, particularly for some type of makeup that will create a high definition color pattern on the skin, then individual membranes with individual reservoirs of color cosmetic compounds per single microneedle would be preferred, such as depicted in Figures 58 and 60. The delivery mechanism would then be a consideration, and if it is desired for the delivery mechanism to be more or less automatic, then the enclosed microneedle patch structure 1500 of Figure 58 would be used, which has a battery 1524, electrochemical gas generator 1522, and an internal volume or cavity at 1520 that will be pressurized to dispense the ingredients through the microneedles.

On the other hand, if the delivery mechanism can be manual rather than automatic, then the microneedle patch 1550 illustrated in Figure 60 could be used, in which the individual membranes 1514 would be actuated by a human finger, such as that finger 1540 in Figure 61.

If the color of the cosmetic compound/nutrient/skin structure improvement ingredient will be only a single color and have the same chemical composition, then the microneedle patch structure 1600 illustrated in Figure 62 could be utilized, or the microneedle patch 1650 illustrated in Figure 65. Again, the difference is the delivery mechanism. If delivery should be automatic for some applications, then the enclosed structure 1600 would be recommended, having the battery 1624, large flexible membrane 1614, electrochemical gas generator 1622, and enclosed cavity 1620. On the other hand, if manual delivery by tactile means is acceptable or desirable, then the microneedle patch structure 1650 could be used, and a person's finger could be the actuating mechanism.

The fabrication of the microneedle patches used to dispense color cosmetics/nutrients/skin structure improvement ingredients would be similar to the microneedle patches used to provide marking or tattooing capabilities. It is preferred that

the microneedle array be constructed of high strength plastic, such as nylon or PMMA using micromolding methods such as LIGA or LIGA-like processes, including hot embossing, or hot embossing with silicon or silicon carbide molds that are microfabricated by conventional micromachining. The flexible membrane is then attached to the base of each microneedle by membrane transfer microfabrication methods. The reservoirs formed thereby are then filled with color cosmetics or skin supporting polymers in order to form the desired color or structure pattern, and then temporarily sealed by attaching a plastic film (e.g., film 1602 on Figure 62). Certain microneedle points could be glued or otherwise permanently sealed to prevent the dispensing of any compound through those particular hollow microneedles.

The color cosmetics or skin support structures could be made monochrome, and therefore, a single large reservoir could be used to dispense the compounds through all of the appropriate microneedles, as depicted in Figures 62 and 65, for example. On the other hand, if a color pattern is desired, then the individual small reservoirs per microneedle would be used, as per the designs illustrated in Figures 58 and 60.

When it is time to apply the subcutaneous makeup to the skin, the human consumer or user selects a microneedle patch having the desired pattern or ingredients. The protective plastic film is stripped away (e.g., the film 1602 on Figure 62) from the microneedle array. The microneedle patch is then applied to the skin, and the electrochemical gas generator is activated by pressing a switch button on the microneedle patch. The gas thereby produced forces the flexible membranes (or single flexible membrane) that covers the makeup ingredients to be forced through the openings in the respective microneedles, and into the epidermis. Alternatively, the microneedle patch could be operated manually, as described above. Once the makeup ingredients have been injected, the microneedle patch is discharged, although it certainly could be made as a reusable device, if desired.

In addition to creating color patterns by use of color cosmetics, the microneedle patch of the present invention can dispense skin structure improvement ingredients or nutrients, such as polymers that can be used to remove wrinkles. Other types of skin structure modifiers can also be applied through the microneedle patch, including such

ingredients as fat, collagen, botulinum toxin, fibril, silicones, hydrogels, elastomers, and colloids. In addition, a semi-permanent lipstick compound could be applied directly to human lips, and the coloring thereby introduced to the lip skin would be semi-permanent from the standpoint that it would last for at least one month, and possibly up to three months. If the microneedles are made short enough that their structure only penetrates into the epidermis, then there would be no pain involved in using the microneedle patch virtually anyplace on the human body. Moreover, there would be very little danger of infection or other type of toxic effects.

Figure 67 illustrates a microneedle patch 1700 consisting of solid microneedles 1710, which are of sufficient length to penetrate into the epidermis, but not into the dermis (in this particular configuration). Of course, longer microneedles could be used to penetrate directly into the dermis, if desired. The microneedles 1710 are supported by a substrate material at 1720.

In the configuration of Figure 67, the solid microneedles 1710 are used to create multiple tiny openings in the skin through the stratum corneum 540 and into the epidermis 542 (but not into the dermis 544). The human user manually applies the patch 1700 onto the skin by holding and pressing the substrate layer 1720 against the surface of the skin, thereby pushing the solid microneedles 1710 into the skin. This can be done either just before or just after application of a fluidic substance containing particles or an active, such as color cosmetics, skin structure improvement ingredients or nutrients, or skin structure modifiers, such as polymers, fat, collagen, or any of the list of compounds as noted hereinabove.

The fluidic compound used to transfer particles into the skin can comprise a liquid-type or cream-type substance, or an ointment, which is applied directly to the skin. If the fluidic compound is applied first, then the microneedle patch 1700 will preferably be pressed against the skin in the same area very soon thereafter. The microneedle patch 1700 would be applied for about ten (10) seconds, then removed from the skin surface. Some of the fluidic compound already on the skin surface would be forced into the tiny holes made in the skin as the microneedle patch 1700 is pressed onto the skin, and other portions of the fluidic compound would then soak into the skin through the tiny holes left

behind after the microneedle patch 1700 has been removed from the skin surface. If desired, the skin having the fluidic compound can be further rubbed to assist in penetration of the compound into the epidermis.

If the fluidic compound is applied after application of the microneedle patch 1700, then the procedure is as follows: press the microneedle patch 1700 against the skin for about ten (10) seconds, then remove the patch from the skin surface. Shortly thereafter, apply the fluidic compound (in the form of a liquid, cream, or ointment) directly onto the same area of the skin. This should take place within an hour after the application of the microneedle patch 1700 against the skin, preferably sooner. The skin having the fluidic compound can be further rubbed to assist in penetration of the compound into the epidermis. Then leave the fluidic compound on the skin surface for a day.

Another alternative methodology for using the microneedle patch 1700 is to deposit the fluidic compound directly onto the surface of the microneedle array, i.e., on the surface of the solid microneedles 1710 and the adjacent substrate 1720. This deposition could be performed at the factory, such that the microneedle patch 1700 is shipped already containing the fluidic compound, or alternatively, the deposition could be performed by a human user before the microneedle patch 1700 is applied to the skin surface.

The physical deposition of the fluidic compound upon the microneedle array could be accomplished in many different ways known in the art, depending upon whether the fluidic compound is in the form of a liquid, cream, or ointment, and depending upon the viscosity of the fluidic compound. Of course, a liquid having low viscosity is probably not a likely candidate for being applied at the factory, since such a low viscosity liquid would not be prone to remaining in place on the microneedles. On the other hand, an ointment or cream (or even a high viscosity liquid) could be applied at the factory and be expected to remain in place. If the microneedle patch is provided in a one inch by one inch size, for example, then only a relatively small amount of the fluidic compound is required. This approach may be more efficient in usage of the fluidic compound, since it will use only an amount of the fluidic compound required to cover the microneedle patch, rather than having the human user manually cover an area of skin that would likely be larger than the portion of the skin that will actually receive the patch 1700.

The particles in solution or suspension within the fluidic compound will easily penetrate into the epidermis, and will remain there in substantially the same precise locations. This allows for very exacting placement of color materials, such as color cosmetics, to create a pattern of colors that will be visible when viewing the skin.

It will be understood that the solid microneedles 1710 could be of any size and shape without departing from the principles of the present invention. For example, the conical shape of microneedles 1710 is similar to that depicted in Figure 29. However, the "sharp" solid microneedles 900 illustrated in Figures 35 and 36 would do quite nicely for use in the solid microneedle patch 1700. Of course, the through-holes 940, 942, and 944 on Figure 36 are not necessary, as noted above, since the fluid will not be dispensed through the substrate of the microneedle patch.

Moreover, it will be understood that the length of and spacing between the microneedles 1710 could be of any dimensions without departing from the principles of the present invention. It will be further understood that the patch size in length and width of microneedle patch 1700 could be of any dimensions without departing from the principles of the present invention.

The foregoing description of at least one preferred embodiment of the invention has been presented for purposes of illustration and description. It is not intended to be exhaustive or to limit the invention to the precise form disclosed. Obvious modifications or variations are possible in light of the above teachings. The embodiments were chosen and described in order to best illustrate the principles of the invention and its practical application to thereby enable one of ordinary skill in the art to best utilize the invention in various embodiments and with various modifications as are suited to the particular use contemplated. It is intended that the scope of the invention be defined by the claims appended hereto.

What is claimed is:

1. A microneedle array structure, characterized in that it comprises: a plurality of microneedle elements having a first end and a second end, said microneedle elements extending from a base element at said first end of the microneedle elements; and at least one reservoir containing a fluid, said at least one fluid-containing reservoir having a flexible membrane at a first surface and being in communication with at least one of said plurality of microneedle elements at a second surface;

wherein said first surface of the flexible membrane, upon actuation, forces the fluid from said at least one fluid-containing reservoir in a direction toward said at least one of said plurality of microneedle elements.

2. The microneedle array structure as recited in claim 1, further comprising: an enclosed cavity that contains said at least one fluid-containing reservoir and an electrochemical gas generator that, upon activation of an electrical power source, produces a pressurizing gas that actuates said first surface of the flexible membrane.

3. The microneedle array structure as recited in claim 1 or 2, wherein said first surface of the flexible membrane is of a size and structural integrity to withstand a direct tactile actuation.

4. The microneedle array structure as recited in any of claims 1-3, wherein the second end of said plurality of microneedle elements is positioned so as to penetrate a stratum corneum and into an epidermis of skin, and wherein said fluid is dispensed through hollow openings of a predetermined quantity of said plurality of microneedle elements into said epidermis, such that said fluid will become semi-permanently resident in the epidermis until it is expunged by skin renewal.

5. The microneedle array structure as recited in any of claims 1-4, wherein said at least one reservoir comprises a single reservoir that provides fluid to all of a

predetermined set of said plurality of microneedle elements, and thereby dispenses a single fluid of a single color from said plurality of microneedle elements into skin, wherein said single fluid of a single color preferably comprises one of: visible ink, visible dye, fluid containing particles of a visible pigment, ink invisible to unaided human eyes, dye invisible to unaided human eyes, fluid containing particles of a pigment invisible to unaided human eyes, a cosmetic compound, a nutrient, or a skin support structure compound.

6. The microneedle array structure as recited in any of claims 1-4, wherein said at least one reservoir comprises a plurality of individual reservoirs that each provide fluid to a single one of a predetermined set of said plurality of microneedle elements, and thereby dispenses at least one fluid of more than a single color from said plurality of microneedle elements into skin, wherein said at least one fluid of more than a single color preferably comprises one of: visible ink, visible dye, fluid containing particles of a visible pigment, ink invisible to unaided human eyes, dye invisible dye to unaided human eyes, fluid containing particles of a pigment invisible to unaided human eyes, a cosmetic compound, a nutrient, or a skin support structure compound.

7. A method of dispensing a fluid into skin, characterized in that it comprises:
providing a microneedle array structure that includes a plurality of microneedle elements that extend from a base element; and at least one reservoir containing a fluid, said at least one fluid-containing reservoir having a flexible membrane at a first surface and being in communication with at least one of said plurality of microneedle elements at a second surface;

positioning said microneedle array structure on the surface of skin, and pressing said microneedle array structure into said skin; and

actuating said first surface of the flexible membrane to thereby force the fluid from said at least one fluid-containing reservoir in a direction toward said at least one of said plurality of microneedle elements and into said skin,

wherein said fluid preferably comprises one of: a visible ink, a visible dye, a fluid containing particles of a visible pigment, an ink invisible to unaided human eyes, a dye invisible to unaided human eyes, a fluid containing particles of a pigment invisible to unaided human eyes, a cosmetic compound, a nutrient, or a skin support structure compound.

8. The method as recited in claim 7, wherein said microneedle elements penetrate into an epidermis of said skin, and said fluid becomes semi-permanent in said epidermis.

9. The method as recited in claim 7 or 8, further comprising: directly actuating said first surface of the flexible membrane by pressing with a human finger.

10. The method as recited in any of claims 7-9, wherein said cosmetic compound comprises one of: a skin nutrient, makeup, a skin support structure compound, a polymer, a collagen, a lip coloring compound, botulinum toxin, fibril, silicones, hydrogels, elastomers, or colloids.

[Continued on next page]

(54) Title: **MICRONEEDLE APPARATUS USED FOR MARKING SKIN AND FOR DISPENSING SEMI-PERMANENT SUBCUTANEOUS MAKEUP**

(57) Abstract: An array of microneedles is provided to apply semi-permanent or permanent markings to skin, or to apply semi-permanent subcutaneous makeup or other cosmetic compounds to skin. The microneedles can apply identifications or other tattoo-like graphics, and will not enter into the dermal layer of the skin so that the application procedure is painless. The markings can be made permanent or semi-permanent, and can be applied with monochrome or multi-color inks, or even inks that are not visible at human eye wavelengths. The preferred inks contain particles of a certain minimum size that will not diffuse too far through the skin, thereby maintaining a high resolution, and if placed into the epidermis, the marking will disappear from the skin after a

time period. The microneedle array is also useful for delivering specific compounds or actives into the skin, such as cosmetic compounds or nutrients, or various skin structure modifiers that can be delivered subcutaneously without having to visit a cosmetic surgery clinic. In addition, color cosmetics could also be delivered subcutaneously to provide long-term benefits for the skin, and even makeup or lipstick-type coloring compounds can be delivered by use of the microneedle patches described hereinabove. The color cosmetics are delivered into the epidermis, where they remain in place for at least one or two months. Since the epidermis is renewable, the color makeup or color cosmetics that are delivered would eventually wear out, since the epidermis is renewable; the delivered color pigment or dye, or skin structure support actives (such as polymers) will remain in the epidermis for only a finite time (e.g., 1-3 months), and then will be expunged from the body. This allows a person to change their "look" according to changes in fashion and style, which typically change every season.

☒ Patent family members are listed in annex.

* Special categories of cited documents:

- *A* document defining the general state of the art which is not considered to be of particular relevance
- *E* earlier document but published on or after the international filing date
- *L* document which may throw doubts on priority claim(s) or which is cited to establish the publication date of another citation or other special reason (as specified)
- *O* document referring to an oral disclosure, use, exhibition or other means
- *P* document published prior to the international filing date but later than the priority date claimed

- *T* later document published after the international filing date or priority date and not in conflict with the application but cited to understand the principle or theory underlying the invention
- *X* document of particular relevance; the claimed invention cannot be considered novel or cannot be considered to involve an inventive step when the document is taken alone
- *Y* document of particular relevance; the claimed invention cannot be considered to involve an inventive step when the document is combined with one or more other such documents, such combination being obvious to a person skilled in the art.
- *G* document member of the same patent family
